About the Editor

Frank J. Fabozzi is Professor of Finance at EDHEC Business School and a member of the EDHEC Risk Institute. Prior to joining EDHEC in August 2011, he held various professorial positions in finance at Yale University's School of Management from 1994 to 2011 and from 1986 to 1992 was a visiting professor of finance and accounting at MIT's Sloan School of Management. From 2008 to 2011, he was an affiliated professor in the Institute of Statistics, Econometrics, and Mathematical Finance at the University of Karlsruhe in Germany. Prior to 1986 he held professorial positions at Lafayette College, Fordham University, Queens College (CUNY), and Hofstra University. From 2003 to 2011, he served on Princeton University's Advisory Council for the Department of Operations Research and Financial Engineering and since then has been a visiting fellow in that department.

Professor Fabozzi is the editor of the *Journal of Portfolio Management*, as well as on the editorial board of the *Journal of Fixed Income*, *Journal of Asset Management*, *Quantitative Finance*, *Review of Futures Markets*, *Journal of Mathematical Finance*, *Journal of Structured Finance*, *Annals of Financial Economics*, and *Theoretical Economic Letters*.

He has authored and edited a number of books in asset management and quantitative finance. His coauthored books in quantitative finance include *A Probability Metrics Approach to Financial Risk Measures* (2011), *Financial Modeling with Lévy Processes and Volatility Clustering* (2011), *Quantitative Equity Investing: Techniques and Strategies* (2010), *Probability and Statistics for Finance* (2010), *Simulation and Optimization Modeling in Finance* (2010), *Bayesian Methods in Finance* (2008), *Advanced Stochastic Models, Risk Assessment, and Portfolio Optimization: The Ideal Risk* (2008), *Financial Econometrics: From Basics to Advanced Modeling Techniques* (2007), *Robust Portfolio Optimization and Management* (2007), and *Mathematics of Financial Modeling and Investment Management* (2004). His books in applied mathematics include *The Methods of Distances in the Theory of Probability and Statistics* (2013) and *Robust and Non-Robust Models in Statistics* (2009). He coauthored three monographs for the Research Foundation of the CFA Institute: *The Impact of the Financial Crisis on the Asset Management Industry* (2010), *Challenges in Quantitative Equity Management* (2008), and *Trends in Quantitative Finance* (2006).

Professor Fabozzi's research papers have appeared in numerous journals, including *Journal of Finance*, *Journal of Finance and Quantitative Analysis*, *Econometric Theory*, *Operations Research*, *Journal of Banking and Finance*, *Journal of Economic Dynamics and Control*, *Studies in Nonlinear Dynamics and Econometrics*, *European Journal of Operational Research*, *Annals of Operations Research*, *Quantitative Finance*, *European Financial Management*, and *The Econometric Journal*. His 2010 article published in *European Financial Management* with Professors Robert Shiller, and Radu Tunaru, "Property Derivatives for Managing European Real-Estate Risk," received the Best Paper Award and his paper with the same coauthors entitled "A Pricing Framework for Real Estate Derivatives" was awarded

Best Research Paper at the 10th Research Conference Campus for Finance held annually at WHU Otto Beisheim School of Management, Vallendar, Germany. An article coauthored with Dr. Sergio Focardi, "An Autoregressive Conditional Duration Model of Credit Risk Contagion," published in 2005 in *Journal of Risk Finance* was the winner of the 2006 Outstanding Paper by Emerald Literati Network.

He has received several awards and honors for his body of work. In 1994 he was awarded an Honorary Doctorate of Humane Letters from Nova Southeastern University. In 2002 he was inducted into the Fixed Income Analysts Society's Hall of Fame, established by the society "to recognize the lifetime achievements of outstanding practitioners in the advancement of the analysis of fixed-income securities and portfolios." In 2007 he was the recipient of the C. Stewart Sheppard Award given by the CFA Institute "in recognition of outstanding contribution to continuing education in the CFA profession." He was the cover story in the July 1999 issue of *Bloomberg Magazine* entitled "The Boswell of Bonds."

Professor Fabozzi was the co-founder of Information Management Network (now a subsidiary of Euromoney), a conference company specializing in financial topics. He is a trustee for the BlackRock family of closed-end funds where he is the chair of the performance committee and a member of the audit committee. He was a director of Guardian Mutual Funds and Guardian Annuity Funds.

He earned both an M.A. and B.A. in economics and statistics in June 1970 from the City College of New York and elected to Phi Beta Kappa in 1969. He earned a Ph.D. in Economics in September 1972 from the City University of New York. Professor Fabozzi holds two professional designations: Chartered Financial Analyst (1977) and Certified Public Accountant (1982).

Preface

It is often said that investment management is an art, not a science. However, since the early 1990s the market has witnessed a progressive shift toward a more industrial view of the investment management process. There are several reasons for this change. First, with globalization the universe of investable assets has grown many times over. Asset managers might have to choose from among several thousand possible investments from around the globe. Second, institutional investors, often together with their consultants, have encouraged asset management firms to adopt an increasingly structured process with documented steps and measurable results. Pressure from regulators and the media is another factor. Finally, the sheer size of the markets makes it imperative to adopt safe and repeatable methodologies.

In its modern sense, financial modeling is the design (or engineering) of financial instruments and portfolios of financial instruments that result in predetermined cash flows contingent upon different events. Broadly speaking, financial models are employed to manage investment portfolios and risk. The objective is the transfer of risk from one entity to another via appropriate financial arrangements. Though the aggregate risk is a quantity that cannot be altered, risk can be transferred if there is a willing counterparty.

Financial modeling came to the forefront of finance in the 1980s, with the broad diffusion

of derivative instruments. However, the concept and practice of financial modeling are quite old. The notion of the diversification of risk (central to modern risk management) and the quantification of insurance risk (a requisite for pricing insurance policies) were already understood, at least in practical terms, in the 14th century. The rich epistolary of Francesco Datini, a 14th-century merchant, banker, and insurer from Prato (Tuscany, Italy), contains detailed instructions to his agents on how to diversify risk and insure cargo.

What is specific to modern financial modeling is the quantitative management of risk. Both the pricing of contracts and the optimization of investments require some basic capabilities of statistical modeling of financial contingencies. It is the size, diversity, and efficiency of modern competitive markets that makes the use of financial modeling imperative.

This three-volume encyclopedia offers not only coverage of the fundamentals and advances in financial modeling but provides the mathematical and statistical techniques needed to develop and test financial models, as well as the practical issues associated with implementation. The encyclopedia offers the following unique features:

- The entries for the encyclopedia were written by experts from around the world. This diverse collection of expertise has created the most definitive coverage of established and

cutting-edge financial models, applications, and tools in this ever-evolving field.

- The series emphasizes both technical and managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding of the topics and the necessary background to deal with issues related to financial modeling.
- Each entry follows a format that includes the author, entry abstract, introduction, body, listing of key points, notes, and references. This enables readers to pick and choose among various sections of an entry, and creates consistency throughout the entire encyclopedia.
- The numerous illustrations and tables throughout the work highlight complex topics and assist further understanding.
- Each volume includes a complete table of contents and index for easy access to various parts of the encyclopedia.

TOPIC CATEGORIES

As is the practice in the creation of an encyclopedia, the topic categories are presented alphabetically. The topic categories and a brief description of each topic follow.

VOLUME I

Asset Allocation

A major activity in the investment management process is establishing policy guidelines to satisfy the investment objectives. Setting policy begins with the asset allocation decision. That is, a decision must be made as to how the funds to be invested should be distributed among the major asset classes (e.g., equities, fixed income, and alternative asset classes). The term “asset allocation” includes (1) policy asset allocation, (2) dynamic asset allocation, and (3) tactical asset allocation. Policy asset allocation decisions can loosely be characterized as long-term asset allocation decisions, in which the investor seeks to assess an appropriate long-term “normal” asset mix that represents an ideal blend of controlled risk and enhanced return. In dynamic asset allocation the asset mix (i.e., the

allocation among the asset classes) is mechanically shifted in response to changing market conditions. Once the policy asset allocation has been established, the investor can turn his or her attention to the possibility of active departures from the normal asset mix established by policy. If a decision to deviate from this mix is based upon rigorous objective measures of value, it is often called tactical asset allocation. The fundamental model used in establishing the policy asset allocation is the mean-variance portfolio model formulated by Harry Markowitz in 1952, popularly referred to as the theory of portfolio selection and modern portfolio theory.

Asset Pricing Models

Asset pricing models seek to formalize the relationship that should exist between asset returns and risk if investors behave in a hypothesized manner. At its most basic level, asset pricing is mainly about transforming asset payoffs into prices. The two most well-known asset pricing models are the arbitrage pricing theory and the capital asset pricing model. The fundamental theorem of asset pricing asserts the equivalence of three key issues in finance: (1) absence of arbitrage; (2) existence of a positive linear pricing rule; and (3) existence of an investor who prefers more to less and who has maximized his or her utility. There are two types of arbitrage opportunities. The first is paying nothing today and obtaining something in the future, and the second is obtaining something today and with no future obligations. Although the principle of absence of arbitrage is fundamental for understanding asset valuation in a competitive market, there are well-known limits to arbitrage resulting from restrictions imposed on rational traders, and, as a result, pricing inefficiencies may exist for a period of time.

Bayesian Analysis and Financial Modeling Applications

Financial models describe in mathematical terms the relationships between financial random variables through time and/or across assets. The fundamental assumption is that the

model relationship is valid independent of the time period or the asset class under consideration. Financial data contain both meaningful information and random noise. An adequate financial model not only extracts optimally the relevant information from the historical data but also performs well when tested with new data. The uncertainty brought about by the presence of data noise makes imperative the use of statistical analysis as part of the process of financial model building, model evaluation, and model testing. Statistical analysis is employed from the vantage point of either of the two main statistical philosophical traditions—frequentist and Bayesian. An important difference between the two lies with the interpretation of the concept of probability. As the name suggests, advocates of the frequentist approach interpret the probability of an event as the limit of its long-run relative frequency (i.e., the frequency with which it occurs as the amount of data increases without bound). Since the time financial models became a mainstream tool to aid in understanding financial markets and formulating investment strategies, the framework applied in finance has been the frequentist approach. However, strict adherence to this interpretation is not always possible in practice. When studying rare events, for instance, large samples of data may not be available, and in such cases proponents of frequentist statistics resort to theoretical results. The Bayesian view of the world is based on the subjectivist interpretation of probability: Probability is subjective, a degree of belief that is updated as information or data are acquired. Only in the last two decades has Bayesian statistics started to gain greater acceptance in financial modeling, despite its introduction about 250 years ago. It has been the advancements of computing power and the development of new computational methods that have fostered the growing use of Bayesian statistics in financial modeling.

Bond Valuation

The value of any financial asset is the present value of its expected future cash flows. To value

a bond (also referred to as a fixed-income security), one must be able to estimate the bond's remaining cash flows and identify the appropriate discount rate(s) at which to discount the cash flows. The traditional approach to bond valuation is to discount every cash flow with the same discount rate. Simply put, the relevant term structure of interest rate used in valuation is assumed to be flat. This approach, however, permits opportunities for arbitrage. Alternatively, the arbitrage-free valuation approach starts with the premise that a bond should be viewed as a portfolio or package of zero-coupon bonds. Moreover, each of the bond's cash flows is valued using a unique discount rate that depends on the term structure of interest rates and when in time the cash flow is. The relevant set of discount rates (that is, spot rates) is derived from an appropriate term structure of interest rates and when used to value risky bonds augmented with a suitable risk spread or premium. Rather than modeling to calculate the fair value of its price, the market price can be taken as given so as to compute a yield measure or a spread measure. Popular yield measures are the yield to maturity, yield to call, yield to put, and cash flow yield. Nominal spread, static (or zero-volatility) spread, and option-adjusted spread are popular relative value measures quoted in the bond market. Complications in bond valuation arise when a bond has one or more embedded options such as call, put, or conversion features. For bonds with embedded options, the financial modeling draws from options theory, more specifically, the use of the lattice model to value a bond with embedded options.

Credit Risk Modeling

Credit risk is a broad term used to refer to three types of risk: default risk, credit spread risk, and downgrade risk. Default risk is the risk that the counterparty to a transaction will fail to satisfy the terms of the obligation with respect to the timely payment of interest and repayment of the amount borrowed. The counterparty could be the issuer of a debt obligation or an entity on

the other side of a private transaction such as a derivative trade or a collateralized loan agreement (i.e., a repurchase agreement or a securities lending agreement). The default risk of a counterparty is often initially gauged by the credit rating assigned by one of the three rating companies—Standard & Poor’s, Moody’s Investors Service, and Fitch Ratings. Although default risk is the one that most market participants think of when reference is made to credit risk, even in the absence of default, investors are concerned about the decline in the market value of their portfolio bond holdings due to a change in credit spread or the price performance of their holdings relative to a bond index. This risk is due to an adverse change in credit spreads, referred to as credit spread risk, or when it is attributed solely to the downgrade of the credit rating of an entity, it is called downgrade risk. Financial modeling of credit risk is used (1) to measure, monitor, and control a portfolio’s credit risk, and (2) to price credit risky debt instruments. There are two general categories of credit risk models: structural models and reduced-form models. There is considerable debate as to which type of model is the best to employ.

Derivatives Valuation

A derivative instrument is a contract whose value depends on some underlying asset. The term “derivative” is used to describe this product because its value is derived from the value of the underlying asset. The underlying asset, simply referred to as the “underlying,” can be either a commodity, a financial instrument, or some reference entity such as an interest rate or stock index, leading to the classification of commodity derivatives and financial derivatives. Although there are close conceptual relations between derivative instruments and cash market instruments such as debt and equity, the two classes of instruments are used differently: Debt and equity are used primarily for raising funds from investors, while derivatives are primarily

used for dividing up and trading risks. Moreover, debt and equity are direct claims against a firm’s assets, while derivative instruments are usually claims on a third party. A derivative’s value depends on the value of the underlying, but the derivative instrument itself represents a claim on the “counterparty” to the trade. Derivatives instruments are classified in terms of their payoff characteristics: linear and nonlinear payoffs. The former, also referred to as symmetric payoff derivatives, includes forward, futures, and swap contracts while the latter include options. Basically, a linear payoff derivative is a risk-sharing arrangement between the counterparties since both are sharing the risk regarding the price of the underlying. In contrast, nonlinear payoff derivative instruments (also referred to as asymmetric payoff derivatives) are insurance arrangements because one party to the trade is willing to insure the counterparty of a minimum or maximum (depending on the contract) price. The amount received by the insuring party is referred to as the contract price or premium. Derivative instruments are used for controlling risk exposure with respect to the underlying. Hedging is a special case of risk control where a party seeks to eliminate the risk exposure. Derivative valuation or pricing is developed based on no-arbitrage price relations, relying on the assumption that two perfect substitutes must have the same price.

Difference Equations and Differential Equations

The tools of linear difference equations and differential equations have found many applications in finance. A difference equation is an equation that involves differences between successive values of a function of a discrete variable. A function of such a variable is one that provides a rule for assigning values in sequences to it. The theory of linear difference equations covers three areas: solving difference equations, describing the behavior

of difference equations, and identifying the equilibrium (or critical value) and stability of difference equations. Linear difference equations are important in the context of dynamic econometric models. Stochastic models in finance are expressed as linear difference equations with random disturbances added. Understanding the behavior of solutions of linear difference equations helps develop intuition for the behavior of these models. In nontechnical terms, differential equations are equations that express a relationship between a function and one or more derivatives (or differentials) of that function. The relationship between difference equations and differential equations is that the latter are invaluable for modeling situations in finance where there is a continually changing value. The problem is that not all changes in value occur continuously. If the change in value occurs incrementally rather than continuously, then differential equations have their limitations. Instead, a financial modeler can use difference equations, which are recursively defined sequences. It would be difficult to overemphasize the importance of differential equations in financial modeling where they are used to express laws that govern the evolution of price probability distributions, the solution of economic variational problems (such as intertemporal optimization), and conditions for continuous hedging (such as in the Black-Scholes option pricing model). The two broad types of differential equations are ordinary differential equations and partial differential equations. The former are equations or systems of equations involving only one independent variable. Another way of saying this is that ordinary differential equations involve only total derivatives. Partial differential equations are differential equations or systems of equations involving partial derivatives. When one or more of the variables is a stochastic process, we have the case of stochastic differential equations and the solution is also a stochastic process. An assumption must be made about what is driving noise in a stochastic differential

equation. In most applications, it is assumed that the noise term follows a Gaussian random variable, although other types of random variables can be assumed.

Equity Models and Valuation

Traditional fundamental equity analysis involves the analysis of a company's operations for the purpose of assessing its economic prospects. The analysis begins with the financial statements of the company in order to investigate the earnings, cash flow, profitability, and debt burden. The fundamental analyst will look at the major product lines, the economic outlook for the products (including existing and potential competitors), and the industries in which the company operates. The result of this analysis will be the growth prospects of earnings. Based on the growth prospects of earnings, a fundamental analyst attempts to determine the fair value of the stock using one or more equity valuation models. The two most commonly used approaches for valuing a firm's equity are based on discounted cash flow and relative valuation models. The principal idea underlying discounted cash flow models is that what an investor pays for a share of stock should reflect what is expected to be received from it—return on the investor's investment. What an investor receives are cash dividends in the future. Therefore, the value of a share of stock should be equal to the present value of all the future cash flows an investor expects to receive from that share. To value stock, therefore, an investor must project future cash flows, which, in turn, means projecting future dividends. Popular discounted cash flow models include the basic dividend discount model, which assumes a constant dividend growth, and the multiple-phase models, which include the two-stage dividend growth model and the stochastic dividend discount models. Relative valuation methods use multiples or ratios—such as price/earnings, price/book, or price/free cash flow—to determine whether a stock is trading at higher or lower multiples than its peers.

There are two critical assumptions in using relative valuation: (1) the universe of firms selected to be included in the peer group are in fact comparable, and (2) the average multiple across the universe of firms can be treated as a reasonable approximation of “fair value” for those firms. This second assumption may be problematic during periods of market panic or euphoria. Managers of quantitative equity firms employ techniques that allow them to identify attractive stock candidates, focusing not on a single stock as is done with traditional fundamental analysis but rather on stock characteristics in order to explain why one stock outperforms another stock. They do so by statistically identifying a group of characteristics to create a quantitative selection model. In contrast to the traditional fundamental stock selection, quantitative equity managers create a repeatable process that utilizes the stock selection model to identify attractive stocks. Equity portfolio managers have used various statistical models for forecasting returns and risk. These models, referred to as predictive return models, make conditional forecasts of expected returns using the current information set. Predictive return models include regressive models, linear autoregressive models, dynamic factor models, and hidden-variable models.

Factor Models and Portfolio Construction

Quantitative asset managers typically employ multifactor risk models for the purpose of constructing and rebalancing portfolios and analyzing portfolio performance. A multifactor risk model, or simply factor model, attempts to estimate and characterize the risk of a portfolio, either relative to a benchmark such as a market index or in absolute value. The model allows the decomposition of risk factors into a systematic and an idiosyncratic component. The portfolio’s risk exposure to broad risk factors is captured by the systematic risk. For equity portfolios these are typically fundamental factors (e.g., market capitalization and value

vs. growth), technical (e.g., momentum), and industry/sector/country. For fixed-income portfolios, systematic risk captures a portfolio’s exposure to broad risk factors such as the term structure of interest rates, credit spreads, optionality (call and prepayment), credit, and sectors. The portfolio’s systematic risk depends not only on its exposure to these risk factors but also the volatility of the risk factors and how they correlate with each other. In contrast to systematic risk, idiosyncratic risk captures the uncertainty associated with news affecting the holdings of individual issuers in the portfolio. In equity portfolios, idiosyncratic risk can be easily diversified by reducing the importance of individual issuers in the portfolio. Because of the larger number of issuers in bond indexes, however, this is a difficult task. There are different types of factor models depending on the factors. Factors can be exogenous variables or abstract variables formed by portfolios. Exogenous factors (or known factors) can be identified from traditional fundamental analysis or from economic theory that suggests macroeconomic factors. Abstract factors, also called unidentified or latent factors, can be determined with the statistical tool of factor analysis or principal component analysis. The simplest type of factor models is where the factors are assumed to be known or observable, so that time-series data are those factors that can be used to estimate the model. The four most commonly used approaches for the evaluation of return premiums and risk characteristics to factors are portfolio sorts, factor models, factor portfolios, and information coefficients. Despite its use by quantitative asset managers, the basic building blocks of factor models used by model builders and by traditional fundamental analysts are the same: They both seek to identify the drivers of returns for the asset class being analyzed.

Financial Econometrics

Econometrics is the branch of economics that draws heavily on statistics for testing and

analyzing economic relationships. The economic equivalent of the laws of physics, econometrics represents the quantitative, mathematical laws of economics. Financial econometrics is the econometrics of financial markets. It is a quest for models that describe financial time series such as prices, returns, interest rates, financial ratios, defaults, and so on. Although there are similarities between financial econometric models and models of the physical sciences, there are two important differences. First, the physical sciences aim at finding immutable laws of nature; econometric models model the economy or financial markets—artifacts subject to change. Because the economy and financial markets are artifacts subject to change, econometric models are not unique representations valid throughout time; they must adapt to the changing environment. Second, while basic physical laws are expressed as differential equations, financial econometrics uses both continuous-time and discrete-time models.

Financial Modeling Principles

The origins of financial modeling can be traced back to the development of mathematical equilibrium at the end of the nineteenth century, followed in the beginning of the twentieth century with the introduction of sophisticated mathematical tools for dealing with the uncertainty of prices and returns. In the 1950s and 1960s, financial modelers had tools for dealing with probabilistic models for describing markets, the principles of contingent claims analysis, an optimization framework for portfolio selection based on mean and variance of asset returns, and an equilibrium model for pricing capital assets. The 1970s ushered in models for pricing contingent claims and a new model for pricing capital assets based on arbitrage pricing. Consequently, by the end of the 1970s, the frameworks for financial modeling were well known. It was the advancement of computing power and refinements of the theories to take into account real-world market imperfections and

conventions starting in the 1980s that facilitated implementation and broader acceptance of mathematical modeling of financial decisions. The diffusion of low-cost high-performance computers has allowed the broad use of numerical methods, the landscape of financial modeling. The importance of finding closed-form solutions and the consequent search for simple models has been dramatically reduced. Computationally intensive methods such as Monte Carlo simulations and the numerical solution of differential equations are now widely used. As a consequence, it has become feasible to represent prices and returns with relatively complex models. Nonnormal probability distributions have become commonplace in many sectors of financial modeling. It is fair to say that the key limitation of financial modeling is now the size of available data samples or training sets, not the computations; it is the data that limit the complexity of estimates. Mathematical modeling has also undergone major changes. Techniques such as equivalent martingale methods are being used in derivative pricing, and cointegration, the theory of fat-tailed processes, and state-space modeling (including ARCH/GARCH and stochastic volatility models) are being used in financial modeling.

Financial Statement Analysis

Much of the financial data that are used in constructing financial models for forecasting and valuation purposes draw from the financial statements that companies are required to provide to investors. The four basic financial statements are the balance sheet, the income statement, the statement of cash flows, and the statement of shareholders' equity. It is important to understand these data so that the information conveyed by them is interpreted properly in financial modeling. The financial statements are created using several assumptions that affect how to use and interpret the financial data. The analysis of financial statements involves the selection, evaluation, and

interpretation of financial data and other pertinent information to assist in evaluating the operating performance and financial condition of a company. The operating performance of a company is a measure of how well a company has used its resources—its assets, both tangible and intangible—to produce a return on its investment. The financial condition of a company is a measure of its ability to satisfy its obligations, such as the payment of interest on its debt in a timely manner. There are many tools available in the analysis of financial information. These tools include financial ratio analysis and cash flow analysis. Cash flows are essential ingredients in valuation. Therefore, understanding past and current cash flows may help in forecasting future cash flows and, hence, determine the value of the company. Moreover, understanding cash flow allows the assessment of the ability of a firm to maintain current dividends and its current capital expenditure policy without relying on external financing. Financial modelers must understand how to use these financial ratios and cash flow information in the most effective manner in building models.

Finite Mathematics and Basic Functions for Financial Modeling

The collection of mathematical tools that does not include calculus is often referred to as “finite mathematics.” This includes matrix algebra, probability theory, and statistical analysis. Ordinary algebra deals with operations such as addition and multiplication performed on individual numbers. In financial modeling, it is useful to consider operations performed on ordered arrays of numbers. Ordered arrays of numbers are called vectors and matrices while individual numbers are called scalars. Probability theory is the mathematical approach to formalize the uncertainty of events. Even though a decision maker may not know which one of the set of possible events may finally occur, with probability theory a decision maker has the means of providing each event with

a certain probability. Furthermore, it provides the decision maker with the axioms to compute the probability of a composed event in a unique way. The rather formal environment of probability theory translates in a reasonable manner to the problems related to risk and uncertainty in finance such as, for example, the future price of a financial asset. Today, investors may be aware of the price of a certain asset, but they cannot say for sure what value it might have tomorrow. To make a prudent decision, investors need to assess the possible scenarios for tomorrow’s price and assign to each scenario a probability of occurrence. Only then can investors reasonably determine whether the financial asset satisfies an investment objective included within a portfolio. Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). There are important mathematical functions with which the financial modeler should be acquainted. These include the continuous function, the indicator function, the derivative of a function, the monotonic function, and the integral, as well as special functions such as the characteristic function of random variables and the factorial, the gamma, beta, and Bessel functions.

Liquidity and Trading Costs

In broad terms, liquidity refers to the ability to execute a trade or liquidate a position with little or no cost or inconvenience. Liquidity depends on the market where a financial instrument is traded, the type of position traded, and sometimes the size and trading strategy of an individual trade. Liquidity risks are those associated with the prospect of imperfect market liquidity and can relate to risk of loss or

risk to cash flows. There are two main aspects to liquidity risk measurement: the measurement of liquidity-adjusted measures of market risk and the measurement of liquidity risks per se. Market practitioners often assume that markets are liquid—that is, that they can liquidate or unwind positions at going market prices—usually taken to be the mean of bid and ask prices—without too much difficulty or cost. This assumption is very convenient and provides a justification for the practice of marking positions to market prices. However, it is often empirically questionable, and the failure to allow for liquidity can undermine the measurement of market risk. Because liquidity risk is a major risk factor in its own right, portfolio managers and traders will need to measure this risk in order to formulate effective portfolio and trading strategies. A considerable amount of work has been done in the equity market in estimating liquidity risk. Because transaction costs are incurred when buying or selling stocks, poorly executed trades can adversely impact portfolio returns and therefore relative performance. Transaction costs are classified as explicit costs such as brokerage and taxes, and implicit costs, which include market impact cost, price movement risk, and opportunity cost. Broadly speaking, market impact cost is the price that a trader has to pay for obtaining liquidity in the market and is a key component of trading costs that must be modeled so that effective trading programs for executing trades can be developed. Typical forecasting models for market impact costs are based on a statistical factor approach where the independent variables are trade-based factors or asset-based factors.

VOLUME III

Model Risk and Selection

Model risk is the risk of error in pricing or risk-forecasting models. In practice, model risk arises because (1) any model involves simpli-

fication and calibration, and both of these require subjective judgments that are prone to error, and/or (2) a model is used inappropriately. Although model risk cannot be avoided, there are many ways in which financial modelers can manage this risk. These include (1) recognizing model risk, (2) identifying, evaluating, and checking the model's key assumption, (3) selecting the simplest reasonable model, (4) resisting the temptation to ignore small discrepancies in results, (5) testing the model against known problems, (6) plotting results and employing nonparametric statistics, (7) back-testing and stress-testing the model, (8) estimating model risk quantitatively, and (9) reevaluating models periodically. In financial modeling, model selection requires a blend of theory, creativity, and machine learning. The machine-learning approach starts with a set of empirical data that the financial modeler wants to explain. Data are explained by a family of models that include an unbounded number of parameters and are able to fit data with arbitrary precision. There is a trade-off between model complexity and the size of the data sample. To implement this trade-off, ensuring that models have forecasting power, the fitting of sample data is constrained to avoid fitting noise. Constraints are embodied in criteria such as the Akaike information criterion or the Bayesian information criterion. Economic and financial data are generally scarce given the complexity of their patterns. This scarcity introduces uncertainty as regards statistical estimates obtained by the financial modeler. It means that the data might be compatible with many different models with the same level of statistical confidence. Methods of probabilistic decision theory can be used to deal with model risk due to uncertainty regarding the model's parameters. Probabilistic decision making starts from the Bayesian inference process and involves computer simulations in all realistic situations. Since a risk model is typically a combination of a probability distribution model and a risk measure, a critical assumption is the probability distribution assumed for

the random variable of interest. Too often, the Gaussian distribution is the model of choice. Empirical evidence supports the use of probability distributions that exhibit fat tails such as the Student's t distribution and its asymmetric version and the Pareto stable class of distributions and their tempered extensions. Extreme value theory offers another approach for risk modeling.

Mortgage-Backed Securities Analysis and Valuation

Mortgage-backed securities are fixed-income securities backed by a pool of mortgage loans. Residential mortgage-backed securities (RMBS) are backed by a pool of residential mortgage loans (one-to-four family dwellings). The RMBS market includes agency RMBS and nonagency RMBS. The former are securities issued by the Government National Mortgage Association (Ginnie Mae), Fannie Mae, and Freddie Mac. Agency RMBS include passthrough securities, collateralized mortgage obligations, and stripped mortgage-backed securities (interest-only and principal-only securities). The valuation of RMBS is complicated due to prepayment risk, a form of call risk. In contrast, nonagency RMBS are issued by private entities, have no implicit or explicit government guarantee, and therefore require one or more forms of credit enhancement in order to be assigned a credit rating. The analysis of nonagency RMBS must take into account both prepayment risk and credit risk. The most commonly used method for valuing RMBS is the Monte Carlo method, although other methods have garnered favor, in particular the decomposition method. The analysis of RMBS requires an understanding of the factors that impact prepayments.

Operational Risk

Operational risk has been regarded as a mere part of a financial institution's "other" risks. However, failures of major financial entities

have made regulators and investors aware of the importance of this risk. In general terms, operational risk is the risk of loss resulting from inadequate or failed internal processes, people, or systems or from external events. This risk encompasses legal risks, which includes, but is not limited to, exposure to fines, penalties, or punitive damages resulting from supervisory actions, as well as private settlements. Operational risk can be classified according to several principles: nature of the loss (internally inflicted or externally inflicted), direct losses or indirect losses, degree of expectancy (expected or unexpected), risk type, event type or loss type, and by the magnitude (or severity) of loss and the frequency of loss. Operational risk can be the cause of reputational risk, a risk that can occur when the market reaction to an operational loss event results in reduction in the market value of a financial institution that is greater than the amount of the initial loss. The two principal approaches in modeling operational loss distributions are the nonparametric approach and the parametric approach. It is important to employ a model that captures tail events, and for this reason in operational risk modeling, distributions that are characterized as light-tailed distributions should be used with caution. The models that have been proposed for assessing operational risk can be broadly classified into top-down models and bottom-up models. Top-down models quantify operational risk without attempting to identify the events or causes of losses. Bottom-up models quantify operational risk on a micro level, being based on identified internal events. The obstacle hindering the implementation of these models is the scarcity of available historical operational loss data.

Optimization Tools

Optimization is an area in applied mathematics that, most generally, deals with efficient algorithms for finding an optimal solution among a set of solutions that satisfy given constraints. Mathematical programming, a management

science tool that uses mathematical optimization models to assist in decision making, includes linear programming, integer programming, mixed-integer programming, nonlinear programming, stochastic programming, and goal programming. Unlike other mathematical tools that are available to decision makers such as statistical models (which tell the decision maker what occurred in the past), forecasting models (which tell the decision maker what might happen in the future), and simulation models (which tell the decision maker what will happen under different conditions), mathematical programming models allow the decision maker to identify the “best” solution. Markowitz’s mean-variance model for portfolio selection is an example of an application of one type of mathematical programming (quadratic programming). Traditional optimization modeling assumes that the inputs to the algorithms are certain, but there are also branches of optimization such as robust optimization that study the optimal decision under uncertainty about the parameters of the problem. Stochastic programming deals with both the uncertainty about the parameters and a multiperiod decision-making framework.

Probability Distributions

In financial models where the outcome of interest is a random variable, an assumption must be made about the random variable’s probability distribution. There are two types of probability distributions: discrete and continuous. Discrete probability distributions are needed whenever the random variable is to describe a quantity that can assume values from a countable set, either finite or infinite. A discrete probability distribution (or law) is quite intuitive in that it assigns certain values, positive probabilities, adding up to one, while any other value automatically has zero probability. Continuous probability distributions are needed when the random variable of interest can assume any value inside of one or more

intervals of real numbers such as, for example, any number greater than zero. Asset returns, for example, whether measured monthly, weekly, daily, or at an even higher frequency are commonly modeled as continuous random variables. In contrast to discrete probability distributions that assign positive probability to certain discrete values, continuous probability distributions assign zero probability to any single real number. Instead, only entire intervals of real numbers can have positive probability such as, for example, the event that some asset return is not negative. For each continuous probability distribution, this necessitates the so-called probability density, a function that determines how the entire probability mass of one is distributed. The density often serves as the proxy for the respective probability distribution. To model the behavior of certain financial assets in a stochastic environment, a financial modeler can usually resort to a variety of theoretical distributions. Most commonly, probability distributions are selected that are analytically well known. For example, the normal distribution (a continuous distribution)—also called the Gaussian distribution—is often the distribution of choice when asset returns are modeled. Or the exponential distribution is applied to characterize the randomness of the time between two successive defaults of firms in a bond portfolio. Many other distributions are related to them or built on them in a well-known manner. These distributions often display pleasant features such as stability under summation—meaning that the return of a portfolio of assets whose returns follow a certain distribution again follows the same distribution. However, one has to be careful using these distributions since their advantage of mathematical tractability is often outweighed by the fact that the stochastic behavior of the true asset returns is not well captured by these distributions. For example, although the normal distribution generally renders modeling easy because all moments of the distribution exist, it fails to reflect stylized facts commonly encountered in

asset returns—namely, the possibility of very extreme movements and skewness. To remedy this shortcoming, probability distributions accounting for such extreme price changes have become increasingly popular. Some of these distributions concentrate exclusively on the extreme values while others permit any real number, but in a way capable of reflecting market behavior. Consequently, a financial modeler has available a great selection of probability distributions to realistically reproduce asset price changes. Their common shortcoming is generally that they are mathematically difficult to handle.

Risk Measures

The standard assumption in financial models is that the distribution for the return on financial assets follows a normal (or Gaussian) distribution and therefore the standard deviation (or variance) is an appropriate measure of risk in the portfolio selection process. This is the risk measure that is used in the well-known Markowitz portfolio selection model (that is, mean-variance model), which is the foundation for modern portfolio theory. Mounting evidence since the early 1960s strongly suggests that return distributions do not follow a normal distribution, but instead exhibit heavy tails and, possibly, skewness. The “tails” of the distribution are where the extreme values occur, and these extreme values are more likely than would be predicted by the normal distribution. This means that between periods where the market exhibits relatively modest changes in prices and returns, there will be periods where there are changes that are much higher (that is, crashes and booms) than predicted by the normal distribution. This is of major concern to financial modelers in seeking to generate probability estimates for financial risk assessment. To more effectively implement portfolio selection, researchers have proposed alternative risk measures. These risk measures fall into

two disjointed categories: dispersion measures and safety-first measures. Dispersion measures include mean standard deviation, mean absolute deviation, mean absolute moment, index of dissimilarity, mean entropy, and mean colog. Safety-first risk measures include classical safety first, value-at-risk, average value-at-risk, expected tail loss, MiniMax, lower partial moment, downside risk, probability-weighted function of deviations below a specified target return, and power conditional value-at-risk. Despite these alternative risk measures, the most popular risk measure used in financial modeling is volatility as measured by the standard deviation. There are different types of volatility: historical, implied volatility, level-dependent volatility, local volatility, and stochastic volatility (e.g., jump-diffusion volatility). There are risk measures commonly used for bond portfolio management. These measures include duration, convexity, key rate duration, and spread duration.

Software for Financial Modeling

The development of financial models requires the modeler to be familiar with spreadsheets such as Microsoft Excel and/or a platform to implement concepts and algorithms such as the Palisade Decision Tools Suite and other Excel-based software (mostly @RISK1, Solver2, VBA3), and MATLAB. Financial modelers can choose one or the other, depending on their level of familiarity and comfort with spreadsheet programs and their add-ins versus programming environments such as MATLAB. Some tasks and implementations are easier in one environment than in the other. MATLAB is a modeling environment that allows for input and output processing, statistical analysis, simulation, and other types of model building for the purpose of analysis of a situation. MATLAB uses a number-array-oriented programming language, that is, a programming language in which vectors and matrices

are the basic data structures. Reliable built-in functions, a wide range of specialized toolboxes, easy interface with widespread software like Microsoft Excel, and beautiful graphing capabilities for data visualization make implementation with MATLAB efficient and useful for the financial modeler. Visual Basic for Applications (VBA) is a programming language environment that allows Microsoft Excel users to automate tasks, create their own functions, perform complex calculations, and interact with spreadsheets. VBA shares many of the same concepts as object-oriented programming languages. Despite some important limitations, VBA does add useful capabilities to spreadsheet modeling, and it is a good tool to know because Excel is the platform of choice for many finance professionals.

Stochastic Processes and Tools

Stochastic integration provides a coherent way to represent that instantaneous uncertainty (or volatility) cumulates over time. It is thus fundamental to the representation of financial processes such as interest rates, security prices, or cash flows. Stochastic integration operates on stochastic processes and produces random variables or other stochastic processes. Stochastic integration is a process defined on each path as the limit of a sum. However, these sums are different from the sums of the Riemann-Lebesgue integrals because the paths of stochastic processes are generally not of bounded variation. Stochastic integrals in the sense of Itô are defined through a process of approximation by (1) defining Brownian motion, which is the continuous limit of a random walk, (2) defining stochastic integrals for elementary functions as the sums of the products of the elementary functions multiplied by the increments of the Brownian motion, and (3) extending this definition to any function through approximating sequences. The major application of integration to financial modeling involves stochastic

integrals. An understanding of stochastic integrals is needed to understand an important tool in contingent claims valuation: stochastic differential equations. The dynamic of financial asset returns and prices can be expressed using a deterministic process if there is no uncertainty about its future behavior, or, with a stochastic process, in the more likely case when the value is uncertain. Stochastic processes in continuous time are the most used tool to explain the dynamic of financial assets returns and prices. They are the building blocks to construct financial models for portfolio optimization, derivatives pricing, and risk management. Continuous-time processes allow for more elegant theoretical modeling compared to discrete time models, and many results proven in probability theory can be applied to obtain a simple evaluation method.

Statistics

Probability models are theoretical models of the occurrence of uncertain events. In contrast, statistics is about empirical data and can be broadly defined as a set of methods used to make inferences from a known sample to a larger population that is in general unknown. In finance, a particular important example is making inferences from the past (the known sample) to the future (the unknown population). In statistics, probabilistic models are applied using data so as to estimate the parameters of these models. It is not assumed that all parameter values in the model are known. Instead, the data for the variables in the model to estimate the value of the parameters are used and then applied to test hypotheses or make inferences about their estimated values. In financial modeling, the statistical technique of regression models is the workhorse. However, because regression models are part of the field of financial econometrics, this topic is covered in that topic category. Understanding dependences or functional links between variables is a key theme in

financial modeling. In general terms, functional dependencies are represented by dynamic models. Many important models are linear models whose coefficients are correlation coefficients. In many instances in financial modeling, it is important to arrive at a quantitative measure of the strength of dependencies. The correlation coefficient provides such a measure. In many instances, however, the correlation coefficient might be misleading. In particular, there are cases of nonlinear dependencies that result in a zero correlation coefficient. From the point of view of financial modeling, this situation is particularly dangerous as it leads to substantially underestimated risk. Different measures of dependence have been proposed, in particular copula functions. The copula overcomes the drawbacks of the correlation as a measure of dependency by allowing for a more general measure than linear dependence, allowing for the modeling of dependence for extreme events, and being indifferent to continuously increasing transformations. Another essential tool in financial modeling, because it allows the incorporation of uncertainty in financial models and consideration of additional layers of complexity that are difficult to incorporate in analytical models, is Monte Carlo simulation. The main idea of Monte Carlo simulation is to represent the uncertainty in market variables through scenarios, and to evaluate parameters of interest that depend on these market variables in complex ways. The advantage of such an approach is that it can easily capture the dynamics of underlying processes and the otherwise complex effects of interactions among market variables. A substantial amount of research in recent years has been dedicated to making scenario generation more accurate and efficient, and a number of sophisticated computational techniques are now available to the financial modeler.

Term Structure Modeling

The arbitrage-free valuation approach to the valuation of option-free bonds, bonds with em-

bedded options, and option-type derivative instruments requires that a financial instrument be viewed as a package of zero-coupon bonds. Consequently, in financial modeling, it is essential to be able to discount each expected cash flow by the appropriate interest rate. That rate is referred to as the spot rate. The term structure of interest rates provides the relationship between spot rates and maturity. Because of its role in valuation of cash bonds and option-type derivatives, the estimation of the term structure of interest rates is of critical importance as an input into a financial model. In addition to its role in valuation modeling, term structure models are fundamental to expressing value, risk, and establishing relative value across the spectrum of instruments found in the various interest-rate or bond markets. The term structure is most often specified for a specific market such as the U.S. Treasury market, the bond market for double-A rated financial institutions, the interest rate market for LIBOR, and swaps. Static models of the term structure are characterizations that are devoted to relationships based on a given market and do not serve future scenarios where there is uncertainty. Standard static models include those known as the spot yield curve, discount function, par yield curve, and the implied forward curve. Instantiations of these models may be found in both a discrete- and continuous-time framework. An important consideration is establishing how these term structure models are constructed and how to transform one model into another. In modeling the behavior of interest rates, stochastic differential equations (SDEs) are commonly used. The SDEs used to model interest rates must capture the market properties of interest rates such as mean reversion and/or a volatility that depends on the level of interest rates. For a one-factor model, the SDE is used to model the behavior of the short-term rate, referred to as simply the "short rate." The addition of another factor (i.e., a two-factor model) involves extending the SDE to represent the behavior of the short rate and a long-term rate (i.e., long rate).

The entries can serve as material for a wide spectrum of courses, such as the following:

- Financial engineering
- Financial mathematics
- Financial econometrics
- Statistics with applications in finance
- Quantitative asset management
- Asset and derivative pricing
- Risk management

Frank J. Fabozzi
Editor, *Encyclopedia of Financial Models*

Guide to the *Encyclopedia of Financial Models*

The *Encyclopedia of Financial Models* provides comprehensive coverage of the field of financial modeling. This reference work consists of three separate volumes and 127 entries. Each entry provides coverage of the selected topic intended to inform a broad spectrum of readers ranging from finance professionals to academicians to students to fiduciaries. To derive the greatest possible benefit from the *Encyclopedia of Financial Models*, we have provided this guide. It explains how the information within the encyclopedia can be located.

ORGANIZATION

The *Encyclopedia of Financial Models* is organized to provide maximum ease of use for its readers.

Table of Contents

A complete table of contents for the entire encyclopedia appears in the front of each volume. This list of titles represents topics that have been carefully selected by the editor, Frank J. Fabozzi. The Preface includes a more detailed description of the volumes and the topic categories that the entries are grouped under.

Index

A Subject Index for the entire encyclopedia is located at the end of each volume. The sub-

jects in the index are listed alphabetically and indicate the volume and page number where information on this topic can be found.

Entries

Each entry in the *Encyclopedia of Financial Models* begins on a new page, so that the reader may quickly locate it. The author's name and affiliation are displayed at the beginning of the entry. All entries in the encyclopedia are organized according to a standard format, as follows:

- Title and author
- Abstract
- Introduction
- Body
- Key points
- Notes
- References

Abstract

The abstract for each entry gives an overview of the topic, but not necessarily the content of the entry. This is designed to put the topic in the context of the entire *Encyclopedia*, rather than give an overview of the specific entry content.

Introduction

The text of each entry begins with an introductory section that defines the topic under

discussion and summarizes the content. By reading this section, the reader gets a general idea about the content of a specific entry.

Body

The body of each entry explains the purpose, theory, and math behind each model.

Key Points

The key points section provides in bullet point format a review of the materials discussed in

each entry. It imparts to the reader the most important issues and concepts discussed.

Notes

The notes provide more detailed information and citations of further readings.

References

The references section lists the publications cited in the entry.

Equity Models and Valuation

Dividend Discount Models

PAMELA P. DRAKE, PhD, CFA

J. Gray Ferguson Professor of Finance, College of Business, James Madison University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Dividends are cash payments made by a corporation to its owners. Though cash dividends are paid to both preferred and common shareholders, most of the focus of the attention is on the dividends paid to the residual owners of the corporation, the common shareholders. Dividends paid to common and preferred shareholders are not legal obligations of a corporation, and some corporations do not pay cash dividends. But for those companies that pay dividends, changes in dividends are noticed by investors—increases in dividends are viewed favorably and are associated with increases in the company’s stock price, whereas decreases in dividends are viewed quite unfavorably and are associated with decreases in the company’s stock price. Most models that use dividends in the estimation of stock value use current dividends, some measure of historical or projected dividend growth, and an estimate of the required rate of return. Popular models include the basic dividend discount model that assumes a constant dividend growth, and the multiple-phase models, which include the two-stage dividend growth model and the stochastic dividend discount models.

In this entry, we discuss dividend discount models and their limitations. We begin with a review of the various ways to measure dividends and then take a look at how dividends and stock prices are related.

DIVIDEND MEASURES

Dividends are measured using three different measures:

- Dividends per share
- Dividend yield
- Dividend payout

The value of a share of stock today is the investors’ assessment of today’s worth of future cash flows for each share. Because future cash flows to shareholders are dividends, we need a measure of dividends for each share of stock to estimate future cash flows per share. The *dividends per share* is the dollar amount of dividends paid out during the period per share of common stock:

$$\begin{aligned} &\text{Dividends per share} \\ &= \frac{\text{Dividends}}{\text{Number of shares outstanding}} \end{aligned}$$

If a company has paid \$600,000 in dividends during the period and there are 1.5 million shares of common stock outstanding, then

$$\begin{aligned}\text{Dividends per share} &= \frac{\$600,000}{1,500,000 \text{ shares}} \\ &= \$0.40 \text{ per share}\end{aligned}$$

The company paid out 40 cents in dividends per common share during this period.

The *dividend yield*, the ratio of dividends to price, is

$$\begin{aligned}\text{Dividend yield} \\ &= \frac{\text{Annual cash dividends per share}}{\text{Market price per share}}\end{aligned}$$

The dividend yield is also referred to as the dividend-price ratio. Historically, the dividend yield for U.S. stocks has been a little less than 5%, according to a study by Campbell and Shiller (1998). In an exhaustive study of the relation between dividend yield and stock prices, Campbell and Shiller find that:

- There is a weak relation between the dividend yield and subsequent 10-year dividend growth.
- The dividend yield does not forecast future dividend growth.
- The dividend yield predicts future price changes.

The weak relation between the dividend yield and future dividends may be attributed to the effects of the business cycle on dividend growth. The tendency for the dividend yield to revert to its historical mean has been observed by researchers.

Another way of describing dividends paid out during a period is to state the dividends as a portion of earnings for the period. This is referred to as the *dividend payout ratio*:

$$\begin{aligned}\text{Dividend payout ratio} \\ &= \frac{\text{Dividends}}{\text{Earnings available to common shareholders}}\end{aligned}$$

If a company pays \$360,000 in dividends and has earnings available to common shareholders

of \$1.2 million, the payout ratio is 30%:

$$\begin{aligned}\text{Dividend payout ratio} &= \frac{\$360,000}{\$1,200,000} \\ &= 0.30 \text{ or } 30\%\end{aligned}$$

This means that the company paid out 30% of its earnings to shareholders.

The proportion of earnings paid out in dividends varies by company and industry. For example, the companies in the steel industry typically pay out 25% of their earnings in dividends, whereas the electric utility companies pay out approximately 75% of their earnings in dividends.

If companies focus on dividends per share in establishing their dividends (e.g., a constant dividends per share), the dividend payout will fluctuate along with earnings. We generally observe that companies set the dividend policy such that dividends per share grow at a relatively constant rate, resulting in dividend payouts that fluctuate.

DIVIDENDS AND STOCK PRICES

If an investor buys a common stock, he or she has bought shares that represent an ownership interest in the corporation. Shares of common perpetual security—there is no maturity. The investor who owns shares of common stock has the right to receive a certain portion of any dividends—but dividends are not a sure thing. Whether or not a corporation pays dividends is up to its board of directors—the representatives of the common shareholders. Typically, we see some pattern in the dividends companies pay: Dividends are either constant or grow at a constant rate. But there is no guarantee that dividends will be paid in the future.

Preferred shareholders are in a similar situation as the common shareholders. They expect to receive cash dividends in the future, but the payment of these dividends is up to the board of directors. But there are three major differences

between the dividends of preferred and common shares. First, the dividends on preferred stock usually are specified at a fixed rate or dollar amount, whereas the amount of dividends is not specified for common shares. Second, preferred shareholders are given preference: their dividends must be paid before any dividends are paid on common stock. Third, if the preferred stock has a cumulative feature, dividends not paid in one period accumulate and are carried over to the next period. Therefore, the dividends on preferred stock are more certain than those on common shares.

It is reasonable to figure that what an investor pays for a share of stock should reflect what he or she expects to receive from it—return on the investor’s investment. What an investor receives are cash dividends in the future. How can we relate that return to what a share of common stock is worth? Well, the value of a share of stock should be equal to the present value of all the future cash flows an investor expects to receive from that share. To value stock, therefore, an investor must project future cash flows, which, in turn, means projecting future dividends. This approach to the valuation of common stock is referred to as the discounted cash flow approach and the models used are referred to as *dividend discount models*.

Dividend discount models are not the only approach to valuing common stock. There are fundamental factor models, also referred to as multifactor equity models.

BASIC DIVIDEND DISCOUNT MODELS

As discussed above, the basis for the dividend discount model (DDM) is simply the application of present value analysis, which asserts that the fair price of an asset is the present value of the expected cash flows. This model was first suggested by Williams (1938). In the case of common stock, the cash flows are the expected

dividend payouts. The basic DDM model can be expressed mathematically as:

$$P = \frac{D_1}{(1 + r_1)^1} + \frac{D_2}{(1 + r_2)^2} + \dots \quad (1)$$

where

P = the fair value or theoretical value of the common stock

D_t = the expected dividend for period t

r_t = the appropriate discount or capitalization rate for period t

The dividends are expected to be received forever.

Practitioners rarely use the dividend discount model given by equation (1). Instead, one of the DDMs discussed below is typically used.

THE FINITE LIFE GENERAL DIVIDEND DISCOUNT MODEL

The DDM given by equation (1) can be modified by assuming a finite life for the expected cash flows. In this case, the expected cash flows are the expected dividend payouts and the expected sale price of the stock at some future date. The expected sale price is also called the terminal price and is intended to capture the future value of all subsequent dividend payouts. This model is called the *finite life general DDM* and is expressed mathematically as:

$$P = \frac{D_1}{(1 + r_1)^1} + \frac{D_2}{(1 + r_2)^2} + \dots + \frac{D_N}{(1 + r_N)^N} + \frac{P_N}{(1 + r_N)^N} \quad (2)$$

where

P_N = the expected sale price (or terminal price) at the horizon period N

N = the number of periods in the horizon

and P , D_t , and r_t are the same as defined above.

Assuming a Constant Discount Rate

A special case of the finite life general DDM that is more commonly used in practice is one in which it is assumed that the discount rate is constant. That is, it is assumed each r_t is the same for all t . Denoting this constant discount rate by r , equation (2) becomes:

$$P = \frac{D_1}{(1+r)^1} + \frac{D_2}{(1+r)^2} + \cdots + \frac{D_N}{(1+r)^N} + \frac{P_N}{(1+r)^N} \quad (3)$$

Equation (3) is called the constant discount rate version of the finite life general DDM. When practitioners use any of the DDM models presented in this entry, typically the constant discount rate version form is used.

Let's illustrate the finite life general DDM assuming a constant discount rate assuming each period is a year. Suppose that the following data are determined for stock XYZ by a financial analyst:

$$\begin{aligned} D_1 &= \$2.00 & D_2 &= \$2.20 & D_3 &= \$2.30 \\ D_4 &= \$2.55 & D_5 &= \$2.65 \\ P_5 &= \$26 & N &= 5 & r &= 0.10 \end{aligned}$$

Based on these data, the fair price of stock XYZ is

$$\begin{aligned} P &= \frac{\$2.00}{(1.10)^1} + \frac{\$2.20}{(1.10)^2} + \frac{\$2.30}{(1.10)^3} + \frac{\$2.55}{(1.10)^4} \\ &\quad + \frac{\$2.65}{(1.10)^5} + \frac{\$26.00}{(1.10)^5} = \$24.895 \end{aligned}$$

Required Inputs

The finite life general DDM requires three forecasts as inputs to calculate the fair value of a stock:

1. The expected terminal price (P_N)
2. The dividends up to the assumed horizon (D_1 to D_N)
3. The discount rates (r_1 to r_N) or r (in the case of the constant discount rate version)

Thus the relevant question is, How accurately can these inputs be forecasted?

The terminal price is the most difficult of the three forecasts. According to theory, P_N is the present value of all future dividends after N ; that is, D_{N+1} , D_{N+2} , \dots , D_{infinity} . Also, the future discount rate (r_t) must be forecasted. In practice, forecasts are made of either dividends (D_N) or earnings (E_N) first, and then the price P_N is estimated by assigning an "appropriate" requirement for yield, price-earnings ratio, or capitalization rate. Note that the present value of the expected terminal price $P_N/(1+r)^N$ becomes very small if N is very large.

The forecasting of dividends is "somewhat" easier. Usually, past history is available, management can be queried, and cash flows can be projected for a given scenario. The discount rate r is the required rate of return. Forecasting r is more complex than forecasting dividends, although not nearly as difficult as forecasting the terminal price (which requires a forecast of future discount rates as well). As noted above, in practice for a given company r is assumed to be constant for all periods and typically generated from the capital asset pricing model (CAPM). The CAPM provides the expected return for a company based on its systematic risk (beta).

Assessing Fair Value

Given the fair price derived from a dividend discount model, the assessment of the stock proceeds along the following lines. If the market price is below the fair price derived from the model, the stock is undervalued or cheap. The opposite holds for a stock whose market price is greater than the model-derived price. In this case, the stock is said to be overvalued or expensive. A stock trading equal to or close to its fair price is said to be fairly valued.

The DDM tells us the fair price but does not tell us when the price of the stock should be expected to move to this fair price. That is, the model says that based on the inputs generated by the analyst, the stock may be cheap, expensive, or priced appropriately. However, it does

not tell us that if it is mispriced how long it will take before the market recognizes the mispricing and corrects it. As a result, an investor may hold on to a stock perceived to be cheap for an extended period of time and may underperform a benchmark during that period.

While a stock may be mispriced, an investor must also consider how mispriced it is in order to take the appropriate action (buy a cheap stock and sell or sell short an expensive stock). This will depend on the degree of mispricing and transaction costs.

CONSTANT GROWTH DIVIDEND DISCOUNT MODEL

If future dividends are assumed to grow at a constant rate (g) and a single discount rate (r) is used, then the finite life general DDM assuming a constant growth rate given by equation (3) becomes

$$P = \frac{D_0(1+g)^1}{(1+r)^1} + \frac{D_0(1+g)^2}{(1+r)^2} + \frac{D_0(1+g)^3}{(1+r)^3} + \dots + \frac{D_0(1+g)^N}{(1+r)^N} + \frac{P_N}{(1+r)^N} \quad (4)$$

and it can be shown that if N is assumed to approach infinity, equation (4) is equal to:

$$P = \frac{D_0(1+g)}{r-g} \quad (5)$$

Equation (5) is the *constant growth dividend discount model* (Gordon and Shapiro, 1956). An equivalent formulation for the constant growth DDM is

$$P = \frac{D_1}{r-g} \quad (6)$$

where D_1 is equal to $D_0(1+g)$.

Consider a company that currently pays dividends of \$3.00 per share. If the dividend is expected to grow at a rate of 3% per year and the discount rate is 12%, what is the value of a share of stock of this company? Using equation (5),

$$P = \frac{\$3.00(1+0.03)}{0.12-0.03} = \frac{\$3.09}{0.09} = \$34.33$$

If the growth rate for this company's dividends is 5%, instead of 3%, the current value is \$45.00:

$$P = \frac{\$3.00(1+0.05)}{0.12-0.05} = \frac{\$3.15}{0.07} = \$45.00$$

Therefore, the greater the expected growth rate of dividends, the greater the value of a share of stock.

In this last example, if the discount rate is 14% instead of 12% and the growth rate of dividends is 3%, the value of a share of stock is:

$$P = \frac{\$3.00(1+0.03)}{0.14-0.03} = \frac{\$3.09}{0.11} = \$28.09$$

Therefore, the *greater* the discount rate, the *lower* the current value of a share of stock.

Let's apply the model as given by equation (5) to estimate the price of three companies: Eli Lilly, Schering-Plough, and Wyeth Laboratories. The discount rate for each company was estimated using the capital asset pricing model assuming (1) a market risk premium of 5% and (2) a risk-free rate of 4.63%. The market risk premium is based on the historical spread between the return on the market (often proxied with the return on the S&P 500 Index) and the risk-free rate. Historically, this spread has been approximately 5%. The risk-free rate is often estimated by the yield on U.S. Treasury securities. At the end of 2006, 10-year Treasury securities were yielding approximately 4.625%. We use 4.63% as an estimate for the purposes of this illustration. The beta estimate for each company was obtained from the Value Line Investment Survey: 0.9 for Eli Lilly, 1.0 for Schering-Plough and Wyeth. The discount rate, r , for each company based on the CAPM is:

Eli Lilly	$r = 0.0463 + 0.9(0.05) = 9.125\%$
Schering-Plough	$r = 0.0463 + 1.0(0.05) = 9.625\%$
Wyeth	$r = 0.0463 + 1.0(0.05) = 9.625\%$

The dividend growth rate can be estimated by using the compounded rate of growth of historical dividends.

The compound growth rate, g , is found using the following formula:

$$g = \left(\frac{\text{Last dividend}}{\text{Starting dividend}} \right)^{1/\text{no. of years}} - 1$$

This formula is equivalent to calculating the geometric mean of 1 plus the percentage change over the number of years. Using time value of money math, the 2006 dividend is the future value, the starting dividend is the present value, the number of years is the number of periods; solving for the interest rate produces the growth rate.

Substituting the values for the starting and ending dividend amounts and the number of periods into the formula, we get:

Company	1991 dividend	2006 dividend	Estimated annual growth rate
Eli-Lilly	\$0.50	\$1.60	8.063%
Schering-Plough	\$0.16	\$0.22	2.146%
Wyeth	\$0.60	\$1.01	3.533%

The value of D_0 , the estimate for g , and the discount rate r for each company are summarized below:

Company	Current dividend D_0	Estimated annual growth rate g	Required rate of return r
Eli-Lilly	\$1.60	8.063%	9.125%
Schering-Plough	\$0.22	2.146%	9.625%
Wyeth	\$1.01	3.533%	9.625%

Substituting these values into equation (5), we obtain:

$$\begin{aligned} \text{Eli Lilly estimated price} &= \frac{\$1.60(1 + 0.08063)}{0.09125 - 0.08063} \\ &= \frac{\$1.729}{0.0162} = \$162.80 \end{aligned}$$

Schering-Plough estimated price

$$\begin{aligned} &= \frac{\$0.22(1 + 0.02146)}{0.09625 - 0.02146} \\ &= \frac{\$0.225}{0.07479} = \$3.00 \end{aligned}$$

$$\begin{aligned} \text{Wyeth estimated price} &= \frac{\$1.01(1 + 0.03533)}{0.09625 - 0.03533} \\ &= \frac{\$1.046}{0.06092} = \$17.16 \end{aligned}$$

Comparing the estimated price with the actual price, we see that this model does not do a good job of pricing these stocks:

Company	Estimated price at the end of 2006	Actual price at the end of 2006
Eli Lilly	\$162.80	\$49.87
Schering-Plough	\$3.00	\$23.44
Wyeth	\$17.16	\$50.52

Notice that the constant growth DDM is considerably off the mark for all three companies. The reasons include: (1) the dividend growth pattern for none of the three companies appears to suggest a constant growth rate, and (2) the growth rate of dividends in recent years has been much slower than earlier years (and, in fact, negative for Schering-Plough after 2003), causing growth rates estimated from the long time periods to overstate future growth. And this pattern is not unique to these companies.

Another problem that arises in using the constant growth rate model is that the growth rate of dividends may exceed the discount rate, r . Consider the following three companies and their dividend growth over the 16-year period from 1991 through 2006, with the estimated required rates of return:

Company	1991 dividend	2006 dividend	Estimated growth rate g	Estimated required rate of return
Coca Cola	\$0.24	\$1.24	11.70%	7.625%
Hershey	\$0.24	\$1.03	10.198%	7.875%
Tootsie Roll	\$0.04	\$0.31	14.627%	8.625%

For these three companies, the growth rate of dividends over the prior 16 years is greater than the discount rate. If we substitute the D_0 (the 2006 dividends), the g , and the r into equation

(5), the estimated price at the end of 2006 is negative, which doesn't make sense. Therefore, there are some cases in which it is inappropriate to use the constant rate DDM.

The potential for misvaluation using the constant rate DDM is highlighted by Fogler (1988) in his illustration using ABC prior to its being taken over by Capital Cities in 1985. He estimated the value of ABC stock to be \$53.88, which was less than its market price at the time (of \$64) and less than the \$121 paid per share by Capital Cities.

MULTIPHASE DIVIDEND DISCOUNT MODELS

The assumption of constant growth is unrealistic and can even be misleading. Instead, most practitioners modify the constant growth DDM by assuming that companies will go through different growth phases. Within a given phase, dividends are assumed to grow at a constant rate. Molodovsky, May, and Chattiner (1965) were some of the pioneers in modifying the DDM to accommodate different growth rates.

Two-Stage Growth Model

The simplest form of multi-phase DDM is the two-stage growth model. A simple extension of equation (4) uses two different values of g . Referring to the first growth rate as g_1 and the second growth rate as g_2 and assuming that the first growth rate pertains to the next four years and the second growth rate refers to all years following, equation (4) can be modified as:

$$P = \frac{D_0(1+g_1)^1}{(1+r)^1} + \frac{D_0(1+g_1)^2}{(1+r)^2} + \frac{D_0(1+g_1)^3}{(1+r)^3} + \frac{D_0(1+g_1)^4}{(1+r)^4} + \frac{D_0(1+g_1)^5}{(1+r)^5} + \frac{D_0(1+g_1)^6}{(1+r)^6} + \dots$$

which simplifies to:

$$P = \frac{D_0(1+g_1)^1}{(1+r)^1} + \frac{D_0(1+g_1)^2}{(1+r)^2} + \frac{D_0(1+g_1)^3}{(1+r)^3} + \frac{D_0(1+g_1)^4}{(1+r)^4} + P_4$$

Because dividends following the fourth year are presumed to grow at a constant rate g_2 forever, the value of a share at the end of the fourth year (that is, P_4) is determined by using equation (5), substituting $D_0(1+g_1)^4$ for D_0 (because period 4 is the base period for the value at end of the fourth year) and g_2 for the constant rate g :

$$P = \frac{D_0(1+g_1)^1}{(1+r)^1} + \frac{D_0(1+g_1)^2}{(1+r)^2} + \frac{D_0(1+g_1)^3}{(1+r)^3} + \frac{D_0(1+g_1)^4}{(1+r)^4} + \left[\frac{1}{(1+r)^4} \left(\frac{D_0(1+g_1)^4(1+g_2)}{r-g_2} \right) \right] \quad (7)$$

Suppose a company's dividends are expected to grow at 4% rate for the next four years and then 8% thereafter. If the current dividend is \$2.00 and the discount rate is 12%,

$$P = \frac{\$2.08}{(1+0.12)^1} + \frac{\$2.16}{(1+0.12)^2} + \frac{\$2.25}{(1+0.12)^3} + \frac{\$2.34}{(1+0.12)^4} + \left[\frac{1}{(1+0.12)^4} \left(\frac{\$2.53}{0.12-0.08} \right) \right] = \$46.87$$

If this company's dividends are expected to grow at the rate of 4% forever, the value of a share is \$26.00; if this company's dividends are expected to grow at the rate of 8% forever, the value of a share is \$52.00. But because the growth rate of dividends is expected to increase from 4% to 8% in four years, the value of a share is between those two values, or \$46.87.

As you can see from this example, the basic valuation model can be modified to accommodate different patterns of expected dividend growth.

Three-Stage Growth Model

The most popular multiphase model employed by practitioners appears to be the three-stage DDM. (The formula for this model is derived in Sorensen and Williamson [1985].) This model assumes that all companies go through three phases, analogous to the concept of the product life cycle. In the growth phase, a company experiences rapid earnings growth as it produces new products and expands market share. In the transition phase the company's earnings begin

to mature and decelerate to the rate of growth of the economy as a whole. At this point, the company is in the maturity phase in which earnings continue to grow at the rate of the general economy.

Different companies are assumed to be at different phases in the three-phase model. An emerging growth company would have a longer growth phase than a more mature company. Some companies are considered to have higher initial growth rates and hence longer growth and transition phases. Other companies may be considered to have lower current growth rates and hence shorter growth and transition phases.

In the typical investment management organization, analysts supply the projected earnings, dividends, growth rates for earnings, and dividend and payout ratios using fundamental security analysis. The growth rate at maturity for the entire economy is applied to all companies. As a generalization, approximately 25% of the expected return from a company (projected by the DDM) comes from the growth phase, 25% from the transition phase, and 50% from the maturity phase. However, a company with high growth and low dividend payouts shifts the relative contribution toward the maturity phase, while a company with low growth and a high payout shifts the relative contribution toward the growth and transition phases.

STOCHASTIC DIVIDEND DISCOUNT MODELS

As we noted in our discussion and illustration of the constant growth DDM, an erratic dividend pattern such as that of Wyeth can lead to quite a difference between the estimated price and the actual price. In the case of the pharmaceutical companies, the estimated price overstated the actual price for Eli Lilly, but understated the price of Schering-Plough and Wyeth.

Hurley and Johnson (1998a, 1998b) have suggested a new family of valuation model. Their

model allows for a more realistic pattern of dividend payments. The basic model generates dividend payments based on a model that assumes that either the firm will increase dividends for the period by a constant amount or keep dividends the same. The model is referred to as a *stochastic DDM* because the dividend can increase or be constant based on some estimated probability of each possibility occurring. The dividend stream used in the stochastic DDM is called the stochastic dividend stream.

There are two versions of the stochastic DDM. One assumes that dividends either increase or decrease at a constant growth rate. This version is referred to as a binomial stochastic DDM because there are two possibilities for dividends. The second version is called a trinomial stochastic DDM because it allows for an increase in dividends, no change in dividends, and a cut in dividends. We discuss each version below.

Binomial Stochastic Model

For both the binomial and trinomial stochastic DDM, there are two versions of the model—the additive growth model and the geometric growth model. The former model assumes that dividend growth is additive rather than geometric. This means that dividends are assumed to grow by a constant dollar amount. So, for example, if dividends are \$2.00 today and the additive growth rate is assumed to be \$0.25 per year, then next year dividends will grow to \$2.25, in two years dividends will grow to \$2.50, and so on. The second model assumes a geometric rate of dividend growth. This is the same growth rate assumption used in the earlier DDMs presented in this entry.

Binomial Additive Stochastic Model

This formulation of the model is expressed as follows:

$$D_{t+1} = \begin{cases} D_t + C & \text{with probability } p \\ D_t & \text{with probability } 1 - p \end{cases} \quad \text{for } t = 1, 2, \dots$$

where

- D_t = dividend in period t
- D_{t+1} = dividend in period $t+1$
- C = dollar amount of the dividend increase
- p = probability that the dividend will increase

Hurley and Johnson (1998a) have shown that the theoretical value of the stock based on the additive stochastic DDM assuming a constant discount rate is equal to:

$$P = \frac{D_0}{r} + \left[\frac{1}{r} + \frac{1}{r^2} \right] Cp \tag{8}$$

For example, consider once again Wyeth. In the illustration of the constant growth model, we used D_0 of \$1.01 and a g of 3.533%. We estimate C by calculating the dollar increase in dividends for each year that had a dividend increase and then taking the average dollar dividend increase. The average of the increases is \$0.0373.

In the 15-year span 1991 through 2006, dividends increased 11 of the 14 year-to-year differences. Therefore, $p = 11/15 = 73.3333\%$. Substituting these values into equation (8), we find the estimated price to be:

$$P = \frac{\$1.01}{0.09625} + \left[\left(\frac{1}{0.09125} + \frac{1}{0.09125^2} \right) (\$0.03727) \left(\frac{11}{15} \right) \right]$$

$$P = \$10.49351 + [(118.336) (\$0.3727) (0.73333)]$$

$$P = \$10.49351 + \$3.23682 = \$13.73033$$

Applying this model to the other two pharmaceutical companies, we see that the model produces an estimated price that is closer to the actual price than the fair value based on the constant growth model:

Company	Actual price at the end of 2006	Estimated price at the end of 2006 using a constant growth model	Estimated price at the end of 2006 using the binomial additive stochastic model
Eli Lilly	\$49.87	\$162.79	\$29.94
Schering-Plough	\$23.44	\$3.00	\$11.04
Wyeth	\$50.52	\$17.16	\$13.73

Binomial Geometric Stochastic Model

Letting g be the growth rate of dividends, then the geometric dividend stream is

$$D_{t+1} = \begin{cases} D_t(1+g) & \text{with probability } p \\ D_t & \text{with probability } 1-p \end{cases} \text{ for } t = 1, 2, \dots$$

Hurley and Johnson (1998b) show that the price of the stock in this case is:

$$P = \frac{D_0(1+pg)}{r-pg} \tag{9}$$

Equation (9) is the binomial stochastic DDM assuming a geometric growth rate and a constant discount rate.

Trinomial Stochastic Models

The trinomial stochastic DDM allows for dividend cuts. Within the Hurley-Johnson stochastic DDM framework, Yao (1997) derived this model that allows for a cut in dividends. He notes that is not uncommon for a firm to cut dividends temporarily. In fact, an examination of the dividend record of the electric utilities industry as published in *Value Line Industry Review* found that in the aggregate firms cut dividends three times over a 15-year period.

Trinomial Additive Stochastic Model

The additive stochastic DDM can be extended to allow for dividend cuts as follow:

$$D_{t+1} = \begin{cases} D_t + C & \text{with probability } p_U \\ D_t - C & \text{with probability } p_D \\ D_t & \text{with probability } p_C \\ 1 - p_C = 1 - p_U - p_D \end{cases} \text{ for } t = 1, 2, \dots$$

where

- p_U = probability that the dividend will increase
- p_D = probability that the dividend will decrease
- p_C = probability that the dividend will be unchanged

The theoretical value of the stock based on the trinomial additive stochastic DDM then

becomes:

$$P = \frac{D_0}{r} + \left[\frac{1}{r} + \frac{1}{r^2} \right] C(p_U - p_D) \quad (10)$$

Notice that when p_D is zero (that is, there is no possibility for a cut in dividends), equation (10) reduces to equation (8).

Trinomial Geometric Stochastic Model

For the trinomial geometric stochastic DDM allowing for a possibility of cuts, we have:

$$D_{t+1} = \begin{cases} D_t(1+g) & \text{with probability } p_U \\ D_t(1-g) & \text{with probability } p_D \\ D_t & \text{with probability } 1 - p_C \\ & = 1 - p_U - p_D \end{cases} \quad \text{for } t = 1, 2, \dots$$

and the theoretical price is:

$$P = \frac{D_0[1 + (p_U + p_D)]}{r - (p_U - p_D)g} \quad (11)$$

Once again, substituting zero for p_D , equation (11) reduces to equation (9)—the binomial geometric stochastic DDM.

Applications of the Stochastic DDM

Yao (1997) applied the stochastic DDMs to five electric utility stocks that had regular dividends from 1979 to 1994 and found that the models fit the various utility stocks differently.

We see similar results in an updated example using five electric utilities, as shown in Table 1. For three of the five utilities, the binomial model provides an estimate closest to the actual stock price, whereas for the other two utilities, the trinomial model offers the closest estimate. In

none of the cases, however, did the constant dividend growth model offer the closest approximation to the actual stock price.

Advantages of the Stochastic DDM

The stochastic DDM developed by Hurley and Johnson is a powerful tool for the analyst because it allows the analyst to generate a probability distribution for a stock's value. The probability distribution can be used by an analyst to assess whether a stock is sufficiently mispriced to justify a buy or sell recommendation. For example, suppose that a three-phase DDM indicates that the value of a stock trading at \$35 is \$42. According to the model, the stock is underpriced and the analyst would recommend the purchase of this stock. However, the analyst cannot express his or her confidence as to the degree to which the stock is undervalued.

Hurley and Johnson show how the stochastic DDM can be used to overcome this limitation of traditional DDMs. An analyst can use the derived probability distribution from the stochastic DDM to assess the probability that the stock is undervalued. For example, an analyst may find from a probability distribution that the probability that the stock is greater than \$35 (the market price) is 90%.

To employ a stochastic DDM an analyst must be prepared to make subjective assumptions about the uncertain nature of future dividends. Monte Carlo simulation available on a spreadsheet (@RISK in Excel, for example) can then be used to generate the probability distribution.

Table 1 Fit of the Different Dividend Models Applied to Five Electric Utilities

Company	Consolidated Edison	Dominion Resources	FPL Group	PPL	TECO Energy
Actual stock price, end of 2006	\$45.82	\$40.73	\$52.98	\$34.89	\$16.46
Estimated stock price given the . . .					
Constant dividend growth model	\$33.57	\$19.36	\$22.14	\$16.54	\$7.46
Binomial stochastic dividend model	\$43.59	\$30.51	\$36.12	\$28.30	\$23.02
Trinomial stochastic dividend model	\$63.12	\$25.84	\$41.23	\$23.71	\$14.45

EXPECTED RETURNS AND DIVIDEND DISCOUNT MODELS

Thus far, we have seen how to calculate the fair price of a stock given the estimates of dividends, discount rates, terminal prices, and growth rates. The model-derived price is then compared to the actual price and the appropriate action is taken.

The analysis can be recast in terms of expected return. This is found by calculating the return that will make the present value of the expected cash flows equal to the actual price. Mathematically, this is expressed as follows:

$$P_A = \frac{D_1}{(1 + ER)^1} + \frac{D_2}{(1 + ER)^2} + \dots + \frac{D_N}{(1 + ER)^N} + \frac{P_N}{(1 + ER)^N} \quad (12)$$

where

P_A = actual price of the stock
 ER = expected return

The expected return (ER) in equation (12). For example, consider the following inputs used at the outset of this entry to illustrate the finite life general DDM as given by equation (3). For stock XYZ, the inputs assumed are:

$$D_1 = \$2.00 \quad D_2 = \$2.20 \quad D_3 = \$2.30 \\ D_4 = \$2.55 \quad D_5 = \$2.65 \quad P_5 = \$26 \quad N = 5$$

We calculated a fair price based on equation (3) to be \$24.90. Suppose that the actual price is \$25.89. Then the expected return is found by solving the following equation for ER :

$$\begin{aligned} \$25.89 = & \frac{\$2.00}{(1 + ER)} + \frac{\$2.20}{(1 + ER)^2} + \frac{\$2.30}{(1 + ER)^3} \\ & + \frac{\$2.55}{(1 + ER)^4} + \frac{\$2.65}{(1 + ER)^5} + \frac{\$26.00}{(1 + ER)^5} \end{aligned}$$

The expected return is 9%.

The expected return is the discount rate that equates the present value of the expected future cash flows with the present value of the stock. The higher the expected return—for a given set of future cash flows—the lower the

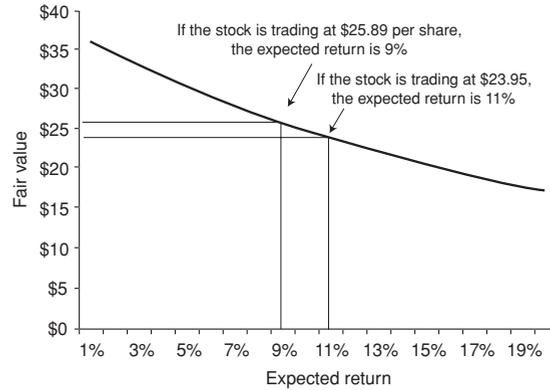

Figure 1 The Relation between the Fair Value of a Stock and the Stock’s Expected Return

current value. The relation between the fair value of a stock and the expected return of a stock is shown in Figure 1.

Given the expected return and the required return (that is, the value for r), any mispricing can be identified. If the expected return exceeds the required return, then the stock is undervalued; if it is less than the required return then the stock is overvalued. A stock is fairly valued if the expected return is equal to the required return. In our illustration, the expected return (9%) is less than the required return (10%); therefore, stock XYZ is overvalued.

With the same set of inputs, the identification of a stock being mispriced or fairly valued will be the same regardless of whether the fair value is determined and compared to the market price or the expected return is calculated and compared to the required return. In the case of XYZ stock, the fair value is \$24.90. If the stock is trading at \$25.89, it is overvalued. The expected return if the stock is trading at \$25.89 is 9%, which is less than the required return of 10%. If, instead, the stock price is \$24.90, it is fairly valued. The expected return can be shown to be 10%, which is the same as the required return. At a price of \$23.95, it can be shown that the expected return is 11%. Since the required return is 10%, stock XYZ would be undervalued.

While the illustration above uses the basic DDM, the expected return can be computed for

any of the models. In some cases, the calculation of the expected return is simple since a formula can be derived that specifies the expected return in terms of the other variables. For example, for the constant growth DDM given by equation (5), the expected return (r) can be easily solved to give:

$$r = \frac{D_1}{P} + g$$

Rearranging the constant growth model to solve for the expected return, we see that the required rate of return can be specified as the sum of the dividend yield and the expected growth rate of dividends.

KEY POINTS

- Dividends are measured in a number of ways, including dividends per share, dividend yield, and dividend payout.
- The discounted cash flow approach to valuing common stock requires projecting future dividends. Hence, the model used to value common stock is called a dividend discount model.
- The simplest dividend discount model is the constant growth model. More complex models include the *multiphase* model and stochastic models.
- Stock valuation using a dividend discount model is highly dependent on the inputs used.
- A dividend discount model does not indicate when the current market price will reach its fair value.
- The output of a dividend discount model is the fair price. However, the model can be used to generate the expected return.
- The expected return is the interest rate that will make the present value of the expected dividends plus terminal price equal to the stock's market price. The expected return is then compared to the required return to assess whether a stock is fairly priced in the market.

Discounted Cash Flow Methods for Equity Valuation

GLEN A. LARSEN Jr., PhD, CFA

Professor of Finance, Indiana University Kelley School of Business—Indianapolis

Abstract: Most applied methods of valuing a firm's equity are based on discounted cash flow and relative valuation models. Although stock and firm valuation is very strongly tilted toward the use of *discounted cash flow* methods, it is impossible to ignore the fact that many analysts use other methods to value equity and entire firms. The primary alternative valuation method is *relative valuation*. Both discounted cash flow and relative valuation methods require strong assumptions and expectations about the future. No one single valuation model or method is perfect. All valuation estimates are subject to *model error* and *estimation error*.

Sound investing requires that an investor does not pay more for an asset than its worth. There are those who argue that value is in the eyes of the beholder, which is simply not true when it comes to financial assets. Perceptions may be all that matter when the asset is an art object or antique automobile, but investors should not buy financial assets for aesthetic or emotional reasons; financial assets are acquired for the cash flows expected from them in future periods. Consequently, perceptions of value have to be backed up by reality, which implies that the price paid for any financial asset should reflect the cash flows that it is expected to generate.

Realize that at the end of the most careful and detailed valuation, there will be uncertainty about the final numbers, biased as they are by the assumptions that we make about the future of the company and the economy. It is unrealistic to expect or demand absolute certainty in valuation, since cash flows and discount rates

are estimated with error. This also means that you have to give yourself a reasonable margin for error in making recommendations on the basis of valuations. Most importantly, realize that the degree of precision in valuations is likely to vary widely across investments. For example, the valuation of a large and mature company, with a long financial history, will usually be much more precise than the valuation of a young company or of a company that is in a sector that is in turmoil.

Implicit often in the act of valuation is the assumption that markets make mistakes and that we can find these mistakes, often using information that tens of thousands of other investors can access. Thus, the argument that those who believe that markets are inefficient should spend their time and resources on valuation whereas those who believe that markets are efficient should take the market price as the best estimate of value, seems to be reasonable.

This statement, though, does not reflect the internal contradictions in both positions. Those who believe that markets are efficient may still feel that valuation has something to contribute, especially when they are called upon to value the effect of a change in the way a firm is run or to understand why market prices change over time.

Furthermore, it is not clear how markets would become efficient in the first place, if investors did not attempt to find under- and over-valued stocks and trade on these valuations. In other words, a precondition for market efficiency seems to be the existence of millions of investors who believe that markets are not.

Stock-pricing models are not physical or chemical laws of nature. There is, however, a strong principle of investing that must eventually hold true for all firms over time if they are to have a positive value. This principle is that you should always be able, in your mind, to construct some sort of logical connection between a positive stock price today and a stream of future cash flows to the investor. The logical chain might be long. You might assume that years of start-up losses (earnings are zero or negative) will be followed by more years of all profits being reinvested. But you should be able to envision some connection between today's positive stock price and a stream of cash flows that will commence someday in the future.

In this entry, we discuss practical methods of valuing a firm's equity based on discounted cash flow (DCF) models. Although stock and firm valuation is very strongly tilted toward the use of DCF methods, it is impossible to ignore the fact that many analysts use other methods to value equity and entire firms. The DCF model is the subject of this entry. The primary alternative valuation method is relative valuation (RV). Both DCF and RV valuation methods require strong assumptions and expectations about the future. No one single valuation model or method is perfect. All valuation estimates are subject to model error and estimation error. Nevertheless, investors use these models to help form their expectations about a *fair market*

price. Markets then generate an observable market clearing price based on investor expectations, and this market clearing price constantly changes along with investor expectations.

DIVIDEND DISCOUNT MODEL

The *dividend discount model* (DDM) is the most basic DCF stock approach to equity valuation, originally formulated by Williams (1938). It states that the stock price should equal the present value of all expected future dividends into perpetuity under the assumption that a firm has an infinite life. But you may also have ignored the DDM once you recognized how difficult it is to apply in the real world. The next several paragraphs simply review the basic concepts in order to highlight the complexities that surround implementing the DDM in practice.

Consider an investor who buys a share of stock, planning to hold it for one year. As you know from previous studies, the *intrinsic value* of the share is the present value, $P(0)$, of the expected dividend to be received at the end of the first year, $ED(1)$, and the expected sales price, $EP(1)$.

$$P(0) = [ED(1) + EP(1)]/(1 + R) \quad (1)$$

Keep in mind that since we live in a world of uncertainty and no human can perfectly forecast the future, future prices and dividends are unknown. Specifically, we are dealing with expected values, not certain values. Under the assumption that dividends can be predictable, given a company's dividend history, the expected future dividend in the next period, $ED(1)$, can be estimated based on historical trends. You might ask how we can estimate $EP(1)$, the expected year-end price.

According to equation (1), the year-end intrinsic value, $P(1)$, will be

$$P(1) = [ED(2) + EP(2)]/(1 + R) \quad (2)$$

If we assume the stock will be selling for its intrinsic value next year, then $P(1) = EP(1)$, and we can substitute equation (2) into equation (1),

which gives

$$P(0) = ED(1)/(1 + R) + [ED(2) + EP(2)]/(1 + R)^2 \quad (3)$$

Equation (3) may be interpreted as the present value of dividends plus the expected sales price at the end of a two-year holding period. Of course, now we need to come up with a forecast of $EP(2)$. Continuing in the same way, we can replace the expected price at the end of two years by the intrinsic value at the end of two years. That is, replace $EP(2)$ by $[ED(3) + EP(3)]/(1 + R)$, which relates $P(0)$ to the value of dividends over three years plus the expected sales price at the end of a three-year holding period.

More generally, for a holding period of T years, we can write the stock value as the present value of dividends over the T years discounted at an appropriate discount rate, R , that is assumed to remain constant, plus the present value of the ultimate sales price, $EP(T)$:

$$P(0) = ED(1)/(1 + R) + ED(2)/(1 + R)^2 + \dots + [ED(T) + EP(T)]/(1 + R)^T \quad (4)$$

In short, the intrinsic price of a share of stock is the present value of a stream of payments (dividends in the case of stocks) and a final payment (the sales price of the stock at time T).

The key problems with implementing this model are the uncertainty of future dividends, the lack of a fixed maturity date, and the unknown sales price at the horizon date and the appropriate discount rate. Indeed, one can continue to substitute for a terminal price on out to infinity (INF):

$$P(0) = ED(1)/(1 + R) + ED(2)/(1 + R)^2 + \dots + ED(INF)/(1 + R)^{INF} \quad (5)$$

Equation (5) states that the stock price should equal the present value of all expected future dividends in perpetuity. This formula is the DDM in mathematical form. It is tempting, but incorrect, to conclude from the equation that the DDM focuses exclusively on dividends and ignores capital gains as a motive for investing in stock. Indeed, we assume explicitly in equation

(4), the finite version of the DDM, that capital gains (as reflected in the expected sales price, $EP(T)$) are part of the stock's value. $EP(T)$ is the present value at time T of all dividends expected to be paid after the horizon date. That value is then discounted back to today, time $T = 0$. The DDM asserts that stock prices are determined ultimately by the cash flows accruing to stockholders, and those are dividends.

Stocks That Currently Pay No Dividend

If investors never expected a dividend to be paid, then this model implies that the stock would have no value. To reconcile the fact that stocks not paying a current dividend do have a positive market value with this model, one must assume that investors expect that someday, at some time T , the firm must pay out some cash, even if only a liquidating dividend.

CONSTANT-GROWTH DDM

The general form of the DDM, as it stands, is still not very useful in valuing a stock because it requires dividend forecasts for every year into the indefinite future. To make the DDM practical, we need to introduce some simplifying assumptions. One useful and common first pass at the problem is to assume that dividends are trending upward at a stable or constant growth rate, g .

For example, if $g = 0.05$ and the most recently paid dividend was $D(0) = 3.81$, expected future dividends are

$$ED(1) = D(0)(1 + g) = (3.81)(1.05) = 4.00$$

$$ED(2) = D(0)(1 + g)^2 = (3.81)(1.05)^2 = 4.20$$

$$ED(3) = D(0)(1 + g)^3 = (3.81)(1.05)^3 = 4.41$$

and so on. Using these dividend forecasts, we can solve for intrinsic value as

$$P(0) = ED(1)/(1 + R) + ED(2)/(1 + R)^2 + ED(3)/(1 + R)^3 + \dots$$

Since the basic form of this equation stretches to infinity, basic algebra allows this equation to

be written as

$$P(0) = ED(1)/(R - g) \quad (6)$$

Equation (6) is called the constant-growth DDM, or the Gordon-Shapiro model, after Myron Gordon and Eli Shapiro, who popularized the model [see Gordon (1962) and Gordon and Shapiro (1956)].

Equation (6) should remind you of the formula for the present value of perpetuity. If dividends were expected not to grow, $g = 0$, then the dividend stream would be a simple perpetuity, and the valuation formula would be

$$P(0) = ED(1)/R$$

$P(0) = ED(1)/(R - g)$ is a generalization of the perpetuity formula to cover the case of a perpetuity growing at a constant rate, g . As g increases, for a given value of $ED(1)$, the stock price rises. The constant-growth DDM is valid only when g is less than R . If dividends were expected to grow forever (to infinity) at a rate faster than R , the value of the stock would be infinite. Further, in all of the DDM equations presented, R is also assumed to be constant forever.

NONCONSTANT-GROWTH DDM

If you feel that you know the future growth rates in each period for a firm, then you can certainly use unique growth rates, $g(T)$ and required rates of return, $R(T)$, in the present value equation and discount all unique dividends and future selling price back to the present. The problem becomes one of time, effort, and estimation risk. At some future point in time, what you believe to be a better unique estimate of a future dividend or a future discount rate will in reality be no better than an assumption of constant growth and constant discount rate.

INTUITION BEHIND THE DDM

In a market economy, common sense dictates that you should go into business only if you expect to make money. In a sole proprietorship, everything left over from the revenue you earned, minus expenses, is yours. In other forms of a business organization, you need to be a bit more formal because there are other owners. In a partnership, partners draw money out of the business. And shareholders get money out of a corporation by receiving dividends. Using the corporate form as an example, the value per share is determined by the value of the dividends distributed to each shareholder. That is, the value per share is determined by the present value of each shareholder's expected share of the profits.

Here is a simple example that illustrates several of the uncertainties involved with the basic DCF valuation process for a share of common stock. Let's say you consider buying shares of a corporation. How much will you pay if the expected annual dividend forever is \$10 per share? That depends on how much of an annual "return" you want. If you want a 10% return, you'll offer \$100 (that is, a \$10 dividend divided by a \$100 investment equals a return of 10%). But just because you offer to pay \$100 doesn't mean someone will sell to you at that price.

Financial capital is subject to principles of market supply and demand, just like commodities. Suppose market conditions are such that prevailing rates of return for corporate shares in this particular risk class are in the 5% range. If I'm selling stock that commands a \$10 per share dividend I can demand a price of \$200, and someone will give it to me. Suppose this corporation is a bit riskier than most others. A buyer may say, "If I'm willing to accept the prevailing 5% return, there are hundreds upon hundreds of better-quality corporations I can invest in. So if you want me to buy your shares, you need to give me incentive to bypass all the others. The buyer and seller may settle on a 7%

return, which is equivalent to a price of about \$143. The appropriate required rate of return, R , is therefore critical, and R can vary with market conditions.

In all cases, assuming that the life of the corporation is infinite, the current price, $P(0)$, is computed as the constant dividend in perpetuity, D , divided by the required rate of return, R , that is, the present value of all future constant dividends. Often, though, investors use return, R , as the basis for comparing and pricing investments. R is often estimated from observable information as D (dividend) divided by current price $P(0)$. Mathematically, it looks like this:

$$R = D/P(0)$$

You've seen this before. It is the dividend yield.

COMPLICATIONS IN IMPLEMENTING THE DDM IN THE REAL WORLD

As you can see by now, there are essentially four major issues that complicate finding the present value of all future dividends and, therefore, in implementing the DDM.

Expected Growth of Dividends

As profits grow over time (as we hope they will), dividends can be expected to grow and not remain constant forever. If profits and dividends are growing by 10% every year, the dividend this year may be \$10, but by next year, it will be \$11. If we divide \$11 by today's \$200 purchase price, next year's yield will be 5.5% ($11/200$). The year after, assuming further 10% growth, the dividend will be \$12.10. Dividing that by the \$200 purchase price produces a yield of 6.05%. The buyer might smile, but the seller won't accept it. The seller wants a price that truly is consistent with the prevailing 5% yield. At \$200, the buyer gets too much of a good deal. If the latter holds the stock over time, he'll wind up with an annual return well in excess of 5%.

Appropriate Expected Required Rate of Return

Simply stated, present value is a tool for computing today's equivalent of a cash payment to be made tomorrow. As stated earlier, this is often referred to as DCF valuation. If I offer you \$10 today or \$10 a year from now, you'll probably choose \$10 today. But if the choice is \$10 today or \$11.50 a year from now, you have to pause. If you can invest today's \$10 payment for one year at 5%, at the end of the year you'll have \$10.50. But if you bypass the \$10 for now and wait, you can get \$11.50 a year hence. That's a better deal. The way to decide if you should wait is to do some mathematics that helps you decide how much you must receive today to allow you to invest and wind up with \$11.50 a year hence. In this example, the "present value" of \$11.50 one year from now, assuming a 5% return, is \$10.95. If I take \$10.95 and invest it for one year at 5%, I'll wind up with \$11.50 at the end of the year. If interest rates rise, to say 8%, it'll take less money today to generate \$11.50 a year hence (\$10.65 will be sufficient). So as interest rates rise, present values fall, and vice versa.

Expected Future Selling Price

Thus far, we have thought about a stream of dividends stretching into the infinite future. Even long-term investors prefer a holding period that's something short of infinity. So we need to account for the fact that someday you'll want to sell your shares. As such, the proceeds you expect to get when you sell are included, along with dividends, in the stream of cash you expect to get, and that goes into the present value calculation.

Let's think about a projection of the future sale price. If you think you may sell in two years, imagine how a prospective buyer, two years into the future, will value the dividend stream that he'll get. Continuing with the preceding example, he'll be looking at an initial payout of

\$12.10 and a 5% return. So a price of \$244 seems a reasonable starting point. Of course, you'll need to make adjustments for probable growth beyond year two. And perhaps 5% won't be appropriate as a rate of return. Market rates may rise or fall, and/or the quality of the corporation may improve or deteriorate relative to alternative investments. And two years hence, the growth forecast may change. But in any case, we do have a \$244 starting point. The changes may bring it up, perhaps to \$275, or down, possibly to \$175. But if an exuberant analyst publishes a target price of \$1,000, you ought to raise an eyebrow and insist that the analyst get serious about justifying his presumably bold assumptions about market rates, growth, or company quality.

Reinvestment of Profits/Internal Financing that Support Growth

It is standard for corporations to refrain from paying out all annual profit as dividend. Some money is held in the business for a rainy day. And some money is simply reinvested for future growth. Either way, profits not paid out as dividends are known as retained earnings. Reinvestment is more desirable than dividend payments if the corporation can earn a higher return on the money than the shareholder could get (by reinvesting the dividends). If all goes well, the reinvestment will enable the corporation to pay a higher dividend in the future than would otherwise have been the case. Going back to the preceding example, if reinvestment gives the corporation the ability to set a year-five payout at \$18 rather than \$12.10, that raises the starting-point target price to \$360. A shareholder who accepts a forecast like that would likely forgo all or some immediate dividend payments in order to get that bigger future reward. As you can see, even if a corporation currently pays little or no dividend, we still have to acknowledge dividends as a major factor in our thoughts about share pricing.

For better or worse, many corporations now see themselves as "growth" companies. And many shareholders have accepted a situation where these publicly traded growth companies pay out very little of their profits, if anything, as dividends, and reinvest most or all profits back into the business. Many companies do not deliver nearly as well on the growth dream as everybody hopes. But the growth culture remains alive and well, and the dividend payout ratio has declined.

ADAPTING TO THE COMPLICATIONS: THE EARNINGS PER SHARE APPROACH

As a result of the four complications listed, modern stock prices have become uncoupled from dividends. So, in the real world, it is difficult to compute a fair price through the basic dividend formulas presented.

Here is one solution. It involves substituting earnings per share (EPS) for dividends. This doesn't really work in a theoretical DDM sense, but it does work within the context of a growth culture. Shareholders have so thoroughly accepted and adopted growth that they act as if all corporate EPS (whether paid as dividends or reinvested back into the business) is in their hands. So, instead of working with a dividend yield as presented earlier, we can substitute an earnings (E) yield, which is computed as follows:

$$\text{Earnings Yield} = E/P$$

Does the E/P ratio look familiar? It should. Turn it upside down and we get something you see all the time: the P/E (price/earnings) ratio.

It is important to emphasize that P/E ratios are not just one of those things we use for the heck of it. They have a serious and solid intellectual underpinning. They are equivalent to earnings yields, which are the modern-day

substitute for dividend yields—the true basis for valuing ownership of corporate stock. So when somebody states that P/E ratios are no longer relevant, you'd best turn away. Buying any stock without addressing the P/E ratio is not sensible.

When we flip P/E back over and think of earnings yield, we can understand, from the prior discussion of dividend yield, that a bad company's stock will have to offer a higher yield to attract buyers. Similarly, the yield for a great company will be low (otherwise, there would be too many would-be buyers). Let's see how this works when we flip the earnings yields back to P/Es.

If EPS equals \$3.00 and the earnings yield is 5%, the price will be \$60. If it's a bad company and the yield is higher, at 8%, the stock price will be \$37.50. If it's a good company and the yield is lower, say 3%, the stock price will be \$100. The starting number translates to a P/E as follows: a \$60 price divided by \$3.00 EPS gives us a P/E of 20. A bad-company stock price of \$37.50 divided by EPS of \$3.00 produces a P/E of 12.5. A good-company stock price of \$100 divided by EPS of \$3.00 produces a P/E of 33.3.

That's the basis for the generally recognized phenomenon of good stocks having higher P/Es and bad stocks generally having lower P/Es. So, once again, this isn't just one of those things. It's an inevitable result of the basic principles of finance and math. When evaluating companies, good or bad is usually determined based on growth prospects and risk.

We handled the complicating factors by treating EPS as if it were the same as a dividend. But notwithstanding, we still have a reasonably rational basis for stock prices. We can argue over what the growth prospects are and what the market return ought to be (based on differing assessments of market conditions and company-quality issues). So there will always be disagreement on what, exactly, a fair stock price ought to be. But all rational investors should be somewhere in the same ballpark. We may have a big ballpark and debate if a stock

that commands \$25 today is worth \$15 or \$35. But we are unlikely to seriously consider a price of, say, \$350.

FREE CASH FLOW DCF MODEL—TOTAL FIRM VALUATION

While estimating future cash flows to an individual share of stock can seem daunting, some investors prefer to estimate the free cash flow to the entire firm. Doing this allows investors to estimate the value of the entire firm and then "back out" an estimated value of a share of stock. This is called the *free cash flow* (FCF) model. While legitimate accounting rules do enable managers and auditors some range of choices, at the end of the day, good companies wind up looking good and bad companies wind up looking bad. In short, there's no one number in an income report that truly gives you the necessary information to value a firm from a discounted expected future cash flow viewpoint. You still have to select which type of cash flow you're going to look at. But the choice becomes very easy once you ask yourself the following question: What's my specific purpose for wanting to know how a company is doing?

There are many different types of users of financial information, and each is best served by concentrating on the information most relevant to him/her. Let's look at various kinds of numbers and consider what they say, and what types of investors will find them most useful.

Generally accepted accounting principles (GAAP) is a set of formal rules that produces what most of us have come to accept as the most official, or standard, version of income that a public corporation can report. Novices often believe this is the only valid number and are perplexed to learn otherwise. Essentially, GAAP is simple: Revenues minus costs equal profits. But the world is a complex place. For our convenience, we divide our activities into time periods. In a simple world, all costs would

be incurred in the same period as the revenues with which they are associated. But that is often not the case, so accountants have to find ways to identify which expenses should be matched against which revenues. One example is depreciation, a concept used to allocate multiperiod costs of a given expense to all the periods in which the expense generates revenue (e.g., if a factory can produce revenue for 10 years, charge one-tenth of the cost to build it against revenue in each year).

Observers correctly note that depreciation rules are artificial, and advocate use of other performance measures that are supposedly more “real.” We’ll touch on this later. But for now, it’s important to understand that depreciation rules are motivated by good purpose. They, and other GAAP rules, are designed to paint a picture of the “economic” performance of the business, something that is not necessarily the same as a running tally of physical dollars coming in and going out within a specific period of time.

If you are looking to see how a company is doing because you want to form an opinion as to whether or not it has a track record of “success” (defined however you wish), GAAP income is very important to you.

As noted, many investors do not like GAAP because of the artificial nature of depreciation. Their objection is valid. GAAP is, indeed, imperfect. Companies have latitude to determine how to calculate it. They don’t always use an equal allocation for each year. It’s difficult, if not impossible, to reliably estimate useful life, especially since assets are usually enhanced (that is, factories modernized) as time passes, thereby giving rise to extended life and additional depreciable expenses tacked on. An assumption that at the end of the depreciation period the asset will be worth zero, or some predetermined salvage value, is often untrue in the real world. And besides, there are other kinds of “artificial” revenue-expense matching formulations to cover other situations. But depreciation is usually the biggest objection.

Difference between Cash Flow and Free Cash Flow

The response is often to add depreciation back to net income to calculate cash flow. This can be a trap for the unwary. The phrase “cash flow” sounds comforting. After all, how much more reliable a gauge of performance can you seek than cash in minus cash out? Read the warning label closely. Is the cash flow you’re seeing truly computed by adding depreciation back to net income? If that’s what’s happening, be very careful. Companies spend money to enhance their assets every year. Because it is understood that the benefits of these expenditures will span many years, they are not put on the income statement in any single year. So, in truth, simple cash flow understates a company’s true cash-in minus cash-out situation. The solution lies in the firm’s free cash flow. To arrive at a firm’s FCF, we start with net income, add back the noncash depreciation charge, and then subtract the year’s capital-spending outlays. (There are other adjustments, such as those relating to dividends and changes in net working capital; but for now, these simple adjustments will suffice.)

Once you hone in on FCF, you aren’t likely to be misled regarding liquidity. But that does not mean you are learning about general corporate success or failure. Capital-spending programs aren’t “smooth.” In some years, expenditures are very large as major programs ramp up. In other years, capital spending shrinks as these programs wind down toward completion. If we’re in a heavy-spending year, FCF could be negative, even though the company may be having a great year.

DCF valuation depends on the construction of pro forma financial statements in order to estimate a firm’s future cash flows. Pro forma is Latin for “as if.” This measure shows how a company might perform in the future “as if” it performs as it has in the past and other assumptions that are made by the analyst. In any event, it is necessary to construct pro forma financial

statements in order to estimate future free cash flows that are the basis for total firm valuation.

CALCULATING FCF

Operating cash flow (OCF) is defined as being equal to earnings before interest and taxes (EBIT) minus taxes plus depreciation. Note, though, that cash flows cannot be maintained over time unless depreciating fixed assets are replaced. That is, the firm must reinvest in those assets that are depreciating (wearing out) so that it can stay alive. Interest paid or any other financing costs such as dividends or principal repaid are not subtracted because we are interested in the cash flow generated by the assets of the firm. The particular mixture of debt and equity a firm actually chooses to use is a managerial decision and determines how the OCF is distributed between owners (equity holders) and creditors (debt holders). The mixture also determines the firm's weighted average cost of capital (WACC), which impacts the firm's value through the discount rate.

$$\text{OCF} = \text{EBIT} - \text{Taxes} + \text{Depreciation}$$

Net operating profit after tax (NOPAT) is defined as EBIT minus taxes.

$$\text{NOPAT} = \text{EBIT} - \text{Taxes} = \text{EBIT} \times (1 - \text{Tax rate})$$

As a result, OCF can also be written as NOPAT plus any noncash adjustments. Where depreciation is the only noncash adjustment:

$$\text{OCF} = \text{NOPAT} + \text{Depreciation}$$

Free cash flow is defined as being the cash flow actually available for distribution to investors after the company has made all the investments in fixed assets and working capital necessary to sustain ongoing operations. To be more specific, the value of a company's operations depends on all the future expected FCFs, defined as OCF minus the amount of investment in working capital and fixed assets necessary to sustain the business. Thus, FCF represents the cash that is actually available for distribution to investors.

Therefore, the way for managers to make their companies more valuable is to create a sustainable increase in the firm's FCF.

$$\begin{aligned} \text{FCF} &= \text{OCF} - \text{Change in NWC} \\ &\quad - \text{Gross investment in operating capital} \end{aligned}$$

Let's illustrate this. Assume a firm has NOPAT of \$170.3 million. Its OCF is NOPAT plus any noncash adjustments as shown on the statement of cash flows. Where depreciation is the only noncash charge, the operating cash flow is:

$$\begin{aligned} \text{OCF} &= \text{NOPAT} + \text{Depreciation} \\ &= \$170.3 + \$100 = \$270.3 \text{ million} \end{aligned}$$

Further, assume the firm had \$1,455 million of operating assets, or operating capital, at the end of the year, but \$1,800 million at the end of the next year. Therefore, during the year:

$$\begin{aligned} \text{Net investment in operating capital} \\ &= \$1,800 - \$1,455 = \$345 \text{ million} \end{aligned}$$

However, the firm took \$100 million of depreciation. We find the gross investment in operating capital as follows:

$$\begin{aligned} \text{Gross investment in operating capital} \\ &= \text{Net investment} + \text{Depreciation} \\ &= \$345 + \$100 = \$445 \text{ million} \end{aligned}$$

FCF in the year is:

$$\begin{aligned} \text{CF} &= \text{OCF} - \text{Gross investment in operating capital} \\ &= \$270.3 - \$445 = -\$174.7 \text{ million (Negative FCF)} \end{aligned}$$

Even though the firm had a positive OCF, its very high investment in operating capital resulted in a negative FCF. Since FCF is what is available for distribution to investors, not only was there nothing for investors, but investors actually had to provide more money to the firm to keep the business going.

Is a negative FCF always bad? It depends on why the FCF was negative. If FCF was negative because NOPAT was negative, this is a bad sign, because the company probably is experiencing operating problems. Exceptions to this might be start-up companies, or companies

Table 1 Free Cash Flow Statement: Indirect Method

Net Income (Net Earnings)	
+ Depreciation	Depreciation is a noncash expense, and therefore is added back to calculate cash flows.
– Increase in accounts receivable (A/R)	The increase in A/R represents sales that have not yet been collected, and therefore did not produce a cash inflow.
– Increase in inventories	The increase in inventory has not been recognized as part of cost of goods sold (COGS) but was fully paid for, and therefore is deducted from the cash flow.
+ Increase in accounts payable (A/P)	The increase in A/P represents costs that have not yet been paid, and therefore is added back to the cash flow.
+ Increase in taxes payable	Like the increase in A/P, these taxes have not yet been paid.
+ After-tax interest expense	We want to evaluate the operating side of the business and its financial side separately. The interest payment is a financial expense, and therefore we add back the “net interest cost.”
= Operating cash flow (OCF)	
– Gross investment in property, plant, and equipment (PP&E), at cost	Some of the cash from operations must be used to buy the assets, such as equipment and plants that will allow the firm to generate future income. This is cash that cannot be freely used to pay dividends, to buy back shares, to repay loans, and the like, and therefore is deducted from the OCF to arrive at the FCF.
= Free cash flow (FCF)	This is the cash that the firm can use to distribute to any and all of its suppliers of capital, such as stockholders, debt holders, and warrant holders.

that are incurring significant current expenses to launch a new product line. Also, many high-growth companies have positive NOPAT but negative FCF due to new investment in operating assets needed to support growth. There is nothing wrong with profitable growth, but at some point in time FCF must turn positive in order for a firm to have value. We will see this later in a firm valuation example.

USING THE CASH-FLOW STATEMENT TO ARRIVE AT OCF AND FCF

As stated earlier, FCF is a concept that defines the amount of cash that the firm can distribute to security holders. There are two principal techniques to calculate the FCF—the indirect method and the direct method. Tables 1 and 2

Table 2 Free Cash-Flow Statement: Direct Method

Sales	As recorded on the Income Statement
– COGS+SG&A	Cost of goods sold (COGS) + Selling, general and administrative expenses (SG&A)
– Increase in accounts receivable (A/R)	Credit sales are recorded as income but do not generate a cash inflow. Thus, to adjust “sales” to cash basis, we deduct the increase in A/R.
– Increase in inventory	Inventory was paid for and thus represents a cash drain.
+ Increase in accounts payable (A/P)	A/P are expenses not yet paid.
+ Depreciation	Depreciation is not a cash expense and is netted out.
– Tax on operating income	The difference between taxes on operating income and the increase in taxes payable is the tax shield on interest, which we don’t want to include in the OCF
+ Increase in taxes payable	
= Operating cash flow (OCF)	
– Gross investment in property, plant & equipment (PP&E) at cost	
= Free cash flow (FCF)	

illustrate the direct and the indirect methods of converting accounting earnings into FCFs. The indirect approach first converts the net income (NI) to OCF then to FCF. The direct approach converts each item in the income statement to cash basis.

The indirect method of calculating cash flows starts with the firm's NI and makes appropriate adjustments to arrive at a number that shows how much cash the firm has taken in over the period. The adjustments that have to be made to NI are of two types—operational adjustments and financial adjustments. When a firm pays interest, net income is defined as

$$\text{NI} = \text{EBIT} - \text{Interest} - \text{Taxes}$$

$$\text{NI} = \text{EBT} - \text{Taxes}$$

The following adjustments must be made in order to present the results of the business activity of the firm on a cash basis as explained later in this entry.

Adjustments for Changes in Net Working Capital

Adjustments for changes in net working capital (ANWC) are made because not all the sales are made in cash and because not all the firm's expenses are paid out in cash. The term and notation are somewhat misleading: Not all the firm's working capital items are operationally related; since we are interested in cash derived from the ongoing business activity of the firm, we ignore all other current items in our ANWC. Cash and marketable securities are the best example of working capital items that we exclude from our definition of ANWC, as they are the firm's stock of excess liquidity. Another working capital item that we exclude from the adjustment is notes payable or short-term borrowing. Since our aim in the FCF statement is to calculate the cash available to the firm from its business activities, we exclude from the FCF statement any cash flows relating to the

firm's financing activities—short term or long term.

Adjustments for Investment in New Fixed Assets

When investment in these assets is necessary for the ongoing business activity of the firm, it cannot be used to pay security holders and thus must be deducted to calculate the FCF.

Adjustments for Depreciation and Other Noncash Expenses

Although depreciation is an expense for tax and financial reporting purposes (thus lowering earnings before taxes [EBT] and hence profits after taxes—[NI]), it is by itself not a cash expense. In the FCF statement, we thus add the depreciation back to NI. The remaining effect of depreciation and other noncash expenses on the FCF is the tax savings they entail.

Financial Adjustments

Financial adjustments are adjustments for financial items included in NI. Since FCF is a concept that relates to the ongoing business (as opposed to financial) activities of the firm, we want to neutralize financial items when converting NI into FCF. Thus, for example, although NI includes interest as an expense, we will add back the after-tax interest expenses to obtain the FCF.

The concept of FCF is of cash flows that are generated by the business activities of the firm and are available (that is, "free") for distribution to all suppliers of capital, such as equity holders, bondholders, convertible holders, and preferred stockholders. The calculation of accounting earnings (net income), however, is done from the point of view of shareholders, which is only one group of capital suppliers.

After calculating the FCFs, we consider their uses. The FCFs can be paid to any security holder of the firm, such as debt holders,

Table 3 Cash Flow Statement

Periodic payments	Interest Preferred dividend Regular dividend And so on	These periodic payments to the capital suppliers of the firm are after tax! (The free cash flows [FCFs] from which we pay these financial flows are also after-tax cash flows!)
Capital market transactions	Retirement of securities Debt retirement Preferred stock retirement Share repurchase And so on New financing New bank loans New bond flotation Stock sale Exercise of warrants And so on	These sums represent cash paid when old securities are retired or represent cash received when new securities are affiliated (privately or publicly).
Change in cash	=FCF – financial cash flows	

stockholders, warrant holders, and convertible bondholders.

The cash flows paid to the security holders are the financial cash flows, which include interest, dividends, principal repayment, share repurchases, and funds received upon the issuance of new securities. Obviously, when the FCF is negative (e.g., because growth opportunities necessitate large investments in fixed assets), the financial cash flows must be a net inflow of funds net new financing (of, say, the needed investments).

The difference between the funds generated by the firm's business, the FCF, and the funds distributed to the security holders of the firm, the financial cash flows (see Table 3), is the change in cash over the period.

Thus, the bottom line of the cash flow statement is the closing link of the three accounting statements of financial performance:

- The income statement's bottom line-retained earnings feeds into the closing balance sheet as the increase in accumulated retained earnings.
- The income statement and the beginning and closing balance sheets are the basis for the computation of the cash flow statements.

- The last line of the cash flow statement—change in cash (and cash equivalents)—feeds back into the end-of-period balance sheet's cash account.

The cross-reference of the three accounting statements means that we can use accounting methods to ensure that models of projected financial performance are internally consistent. The firm's income statement and its cash flow statement are often the basis for predictions of its future FCFs. Note, however, that these statements reflect the past performance of the firm and are not, in themselves, necessarily predictive of future firm performance.

VALUING THE TOTAL FIRM

Earlier we introduced several equations for valuing a firm's common stock. For example, review the constant growth dividend discount model and the nonconstant growth dividend discount model. These models (equations) have one common element: They all assume that the firm is currently paying a dividend. However, consider the situation of a start-up company formed to develop and market a new product. Such a company generally expects to have

low sales during its first few years as it develops and begins to market its product. Then, if the product catches on, sales will grow rapidly for several years. Growing sales require additional assets. A company cannot grow without increasing its assets. Moreover, increasing a liability and/or equity account must finance asset growth.

Small firms can often obtain some bank credit, but they must maintain a reasonable balance between debt and equity. Thus, additional bank borrowings require increases in equity, but small firms have limited access to the stock market. Moreover, even if they can sell stock, their owners are often reluctant to do so for fear of losing voting control. Therefore, the best source of equity for most small businesses is from retaining earnings, so most small firms pay no dividends during their rapid-growth years. Eventually, most successful firms do pay dividends, with dividends growing rapidly at first but then slowing down as the firm approaches maturity.

Although most larger firms do pay a dividend, some firms, even highly profitable ones, have never paid a dividend. How can the value of such a company be determined? Similarly, suppose you start a business and someone offers to buy it from you. How could you determine its value, or that of any privately held business? Alternatively, suppose you work for a company with a number of divisions. How could you determine the value of one particular division that the company wants to sell? In none of these cases could you use the dividend growth model. However, you could use the FCF model to estimate total firm value, then back out the value of equity.

ESTIMATING TOTAL FIRM VALUE USING THE FCF MODEL

Tables 4 and 5 contain the actual 20X8 and projected 20X9 to 20Y2 financial statements for

XYZ Inc. The negative FCF in the early years is typical for young, high-growth companies. Even though NOPAT is positive in all years, FCF is negative because of the need to invest in operating assets. The negative FCF means the company will have to obtain new funds from investors, and the balance sheets in Table 5 show that notes payable, long-term bonds, and preferred stock all increase from 20X8 to 20X9.

Assume that XYZ's cost of capital is 10.84%. To find its going-concern value, we use an approach similar to the nonconstant dividend growth model, proceeding as follows:

1. Assume that the firm will experience nonconstant growth for N years, after which it will grow at some constant rate.
2. Calculate the expected FCF for each of the N nonconstant growth years, and find the present value (PV) of these cash flows.
3. Recognize that after Year N growth will be constant, so we can use the constant growth formula to find the firm's value at Year N . This "terminal value" is the value of the PVs for $N + 1$ and all subsequent years (to infinity), discounted back to Year N . Then, the Year N value must be discounted back to the present to find its PV at Year 0.
4. Now sum all the PVs, those of the annual free cash flows during the nonconstant period plus the PV of the terminal value, to find the firm's value of operations. This going-concern value, when added to the value of the nonoperating assets, is the total value of the firm.

Stockholders will also help fund XYZ's growth. They will receive no dividends until 20Y1, so all of the net income from 20X8 to 20Y1 will be reinvested. However, as growth slows, FCF will become positive, and XYZ plans to use some of its FCF to pay dividends beginning in 20Y1. A variant of the constant growth dividend model can be used to find the value of XYZ's operations once its FCF stabilize and begin to grow at a constant rate:

Table 4 XYZ Inc.: Income Statements (in millions except for per-share data)

	Actual 20X8	Projected			
		20X9	20Y0	20Y1	20Y2
Net sales	\$700.00	\$850.00	\$1,000	\$1,100	\$1,500
Costs (except depreciation)	(599)	(734)	(911)	(935)	(982)
Depreciation	(28)	(31)	(34)	(36)	(38)
Total operating costs	(627)	(765)	(945)	(971)	(1,020)
Earnings before interest and taxes (EBIT)	73	85	55	129	135
Less "net interest"	(13)	(15)	(16)	(17)	(19)
Earnings before taxes	60	70	39	112	116
Taxes (40%)	(24)	(28)	(15.6)	(44.8)	(46.4)
Net income before preferred dividends	36	42	23.4	67.2	69.6
Preferred dividends	(6)	(7)	(7.4)	(8)	(8.3)
Net income available for common dividends	30	35	16	59.2	61.3
Common dividends	—	—	—	44.2	45.3
Addition to retained earnings	30	35	16	15	16
Number of shares	100	100	100	100	100
Dividends per share	—	—	—	0.442	0.453

Notes:

1. "Net interest" is interest paid on debt less interest earned on marketable securities. Both items could be shown separately on the income statements, but for this example we combine them and show net interest.
2. Net income is projected to decline in 20Y0. This is due to a projected cost for a one-time marketing program in that year.
3. Growth has been rapid in the past, but the market is becoming saturated, so the sales growth rate is expected to decline from 21% in 20X9 to a sustainable rate of 5% in 20Y2 and beyond (forever). Further, the entire economy has seldom grown more than a 4% to 6% rate on an average annual basis. If one firm were to grow faster than 6% forever, it would most likely become the only firm in the economy! Therefore, a 5% growth rate beyond year 20Y2 is a reasonable assumption. Firms cannot grow faster than the overall economy forever. Growth must slow down at some point in the future to a more sustainable average rate.
4. Profit margins are expected to improve as the production process becomes more efficient and because XYZ will no longer be incurring marketing costs associated with the introduction of a major product.
5. All items on the financial statements are projected to grow at a 5% rate after the year 20Y2. Notice that the company does not pay a dividend, but it is expected to start paying out about 75% of its earnings beginning in 20Y1.
6. A firm's value is determined by its ability to generate cash flow, both now and in the future. Therefore, XYZ's value can be calculated as the present value of its expected future FCFs from operations, discounted at its cost of capital, k , plus the value of nonoperating assets. Here is the equation for the value of operations, or the firm's value as a going concern:

$$\text{Value of operations} = \text{Present value of expected future FCF} + \text{Present value of nonoperating assets}$$

Based on a 10.84% cost of capital, a \$49 million FCF in 20Y2, and a 5% growth rate, the value of XYZ's operations as of December 31, 20Y2 (terminal value) is forecasted to be \$880.99 million:

$$\begin{aligned} \text{Terminal value} &= \frac{\$49(1 + 0.05)}{(0.1084 - 0.050)} \\ &= \frac{\$51.45}{(0.1084 - 0.05)} = \$880.99 \end{aligned}$$

This \$880.99 million figure is called the company's terminal or horizon value, because it is the value at the end of the forecast period. Moreover, this is the amount that XYZ could expect to receive if it sold its operating assets on December 31, 20Y2.

Table 6 shows the free cash flow for each year during the nonconstant growth period, along with the value of operations in 20Y2, at the end of the nonconstant growth period. To find the

Table 5 XYZ Inc.: Balance Sheets (millions of dollars)

	Actual 20X8	Projected			
		20X9	20Y0	20Y1	20Y2
Cash	\$17	\$20	\$22	\$23	\$24
Marketable securities (1)	63	70	80	84	88
Accounts receivable	85	100	110	116	121
Inventories	170	200	220	231	243

Common equity	245	280	296	311	327
Total liabilities and equity	614	700	773	812	852

Notes:

1. All assets except marketable securities are operating assets required to support sales. The marketable securities are financial assets not required in operations.
2. Common equity is shown at par plus paid-in capital. Present value of nonoperating assets.

value of operations as of “today,” December 31, 20X8, we find the PV of each annual cash flow in Table 7, discounting at the 10.84% cost of capital.

The sum of the PVs (all FCFs and the terminal value discounted at 10.84%) is approximately \$615 million. The \$615.27 represents an estimate of the price XYZ could expect to receive if it sold its operating assets today, December 31, 20X8. The total value of any company is the value of its operations plus the value of its nonoperating assets. As the December 31, 20X8, balance sheet in Table 5 shows, XYZ had \$63 million of marketable securities on that date. Unlike operating assets, we do not have to calculate a present value for marketable securities because short-term financial assets as reported on the balance sheet are at, or close to, their market value.

Therefore, XYZ’s total value on December 31, 20X8, is $\$615.27 + \$63.00 = \$678.27$ million. If the company’s total value on December 31,

20X8, is \$678.27 million, what is the value of its common equity?

First, Table 5 shows that notes payable and long-term debt total $\$123 + \$124 = \$247$ million, and these securities have the first claim on assets and income. (Accounts payable and accruals were netted out earlier.) Next, the preferred stock has a claim of \$62 million, and it ranks above the common.

Therefore, the value left for common stockholders is $\$678.27 - \$247 - \$62 = \369.27 million.

Table 8 summarizes the calculations used to find XYZ’s stock value per share. There are 100 million shares outstanding, and their total value is \$369.27 million. Therefore, the value of a single share is \$3.69 ($\$369.27/100 = \3.69).

Much can be learned from the total firm valuation model, so many analysts today use it for all types of valuations. The process of projecting the future financial statements can reveal quite a bit about the company’s operations and

Table 6 Calculating XYZ's Pro Forma Expected Free Cash Flow (in millions)

	Actual 20X8	Projected			
		20X9	20Y0	20Y1	20Y2
Calculation of free cash flow					
Required net operating working capital	\$212	\$250	\$275	\$289	\$303
Required net plant and equipment	279	310	341	358	376
Required net operating assets	\$491	\$560	\$616	\$647	\$679
Required net new investment in operating assets = change in net operating assets from previous year	69	56	31	32	
NOPAT (Net operating profit after taxes)	EBIT \times (1 - Tax rate)	\$51	\$33	\$77.40	\$81
Less: Required investment in operating assets	69	56	31	32	
Free cash flow (FCF)		(\$18)	(\$23)	\$46.40	\$49

Notes:

- NOPAT declines in 20Y0 because of a marketing expenditure projected for that year.
- Table 4 calculates free cash flow for each year. Line 1, with data for 20X8 from the balance sheets in Table 5, shows the required net operating working capital, or operating current assets minus operating current liabilities, for 20X8:

$$\begin{aligned} \text{Required net operating working capital} &= (\text{Cash} + \text{Accounts receivable} + \text{Inventories}) \\ &\quad - (\text{Accounts payable} + \text{Accruals}) \\ &= (\$17.00 + \$85.00 + \$170.00) - (\$17.00 - \$43.00) = \$212.00. \end{aligned}$$

- Line 2 shows required net plant and equipment, and Line 3, which is the sum of Lines 1 and 2, shows the required net operating assets, sometimes called net operating capital. For 20X8, net operating capital is $\$212 + \$279 = \$491$ million.
- Line 4 shows the required net annual addition to operating assets, found as the change in net operating assets from the previous year. For 20X9, the required net investment in operating assets is $\$560 - \$491 = \$69$ million.
- Line 5 shows NOPAT, or net operating profit after taxes. Note that EBIT is operating earnings before taxes, while NOPAT is operating earnings after taxes. Therefore, $\text{NOPAT} = \text{EBIT} (1 - T)$. With 20X9 EBIT of \$85 as shown in Table 5 and a tax rate of 40%, NOPAT as projected for 20X9 is \$51 million:

$$\text{NOPAT} = \text{EBIT}(1 - T) = \$85(1.0 - 0.4) = \$51 \text{ million.}$$

- Although XYZ's operating assets are projected to produce \$51 million of after-tax profits in 20X9, the company must invest \$69 million in new assets in 20X9. Therefore, the FCF for 20X9, shown on Line 7, is a negative \$18 million:

$$\begin{aligned} \text{FCF in 20X9} &= \$51 - \$69 = -\$18.00 \text{ million (negative)} \\ &\quad \text{Present value of nonoperating assets} \end{aligned}$$

Table 7 Process for Finding the Value of Operations Assumes $g = 5\%$ (constant) for Years 12/31/Y2 in Perpetuity

Year	12/31/X8	12/31/X9	12/31/Y0	12/31/Y1	12/31/Y2
FCF		(18.00)	(23.00)	46.40	49.00

7. Estimated value per share	\$3.69

financing needs. Also, such an analysis can provide insights into actions that might be taken to increase the company's value.

KEY POINTS

- The two most commonly used approaches for equity valuation are the discounted cash flow and relative valuation models.
- Despite the fact that equity valuation is very strongly tilted toward the use of discounted cash flow models, it is impossible to ignore the fact that many financial modelers employ relative valuation techniques.
- Expected future cash flow is the true basis for financial value. Take the firms that look

attractive based on “fundamentals” and attempt to estimate their current fair value based on the present value of all expected future cash flows (dividends and future selling price).

- The basic source of estimation risk when using discounted cash flow models in calculating the value of any financial asset is that the present value depends on expected future cash flows and the appropriate discount rates that reflect the risk of the future cash flows. Cash flow valuation models, therefore, rely on assumptions (often extreme).
- With cash flow valuation, the main problem is estimation risk. No financial modeler can correctly and consistently forecast the future. Estimation risk comes from not being able to perfectly forecast future cash flows and discount rates.

Senior Quantitative Analyst, Delaware Investments

Abstract: Relative valuation methods use multiples or ratios, such as price/earnings, price/book, or price/free cash flow, to determine whether a particular firm is trading at higher or lower multiples than its peers. Such methods require the user to choose a suitable universe of firms that are more or less comparable, though this can become difficult for firms with unusual characteristics in terms of product mix or geographical exposure. Relative valuation methods can be useful for portfolio managers who expect to be fully invested at all times, as they provide a practical tool for attempting to capture the “*value premium*” by which firms trading at lower multiples tend to outperform those trading at higher multiples. Implicitly, relative valuation methods assume that the average multiple across the universe of firms can be treated as a reasonable approximation of “*fair value*” for those firms; this may be problematic during periods of *market panic* or *euphoria*.

Much research in corporate finance and similar academic disciplines is tilted toward the use of discounted cash flow (DCF) methods. However, many analysts also make use of *relative valuation* methods, which compare several firms by using multiples or ratios. Multiples that are commonly used for such purposes include *price/earnings*, *price/book*, and *price/free cash flow*.

Relative valuation methods implicitly assume that “*similar*” firms are likely to be valued similarly by investors. Therefore, on average, we would expect that firms that are generally comparable are likely to trade at similar multiples, in terms of price/earnings, price/book, or various other metrics. If this assumption is approximately correct, then relative valuation methods can be used to identify firms

*The material discussed here does not necessarily represent the opinions, methods, or views of Delaware Investments.

that look “cheap” or “expensive” relative to their peers. When a particular firm’s multiples are extremely different from the rest of the universe, this may indicate a potential investment opportunity—though further analysis will likely be required to determine whether there are reasons why such a firm is valued differently from other companies that otherwise appear comparable.

The basis of relative valuation methods is to use one or several ratios to determine whether a firm looks “cheap” or “expensive” by comparison with generally similar firms. Relative valuation methods do not attempt to explain why a particular firm is trading at a particular price; instead, they seek to measure how the market is currently valuing multiple companies, with the underlying assumption that the average multiple for a group of companies is probably a reasonable approximation to overall market sentiment toward that particular industry. In other words, relative valuation work assumes that on average, the share prices of companies in a particular universe are likely to trade at similar multiples relative to their own financial or operating performance. Baker and Ruback (1999) provide a more formal presentation of these concepts. However, it is important to realize that at any particular time, some firms are likely to be trading at higher or lower multiples than would be justified under “fair value.”

Making effective use of relative valuation methods does require careful selection of “similar” companies. Sometimes this is relatively simple, for instance when an analyst is dealing with industries where there are a large number of roughly homogeneous firms providing goods or services that are approximately equivalent. However, sometimes there can be considerable difficulties in identifying “similar” companies, particularly if the firms under consideration are unusually idiosyncratic in terms of their product mix, geographical focus, or market position. In this entry, we will provide some tentative guidance about how to build a universe of *comparable companies*. However, ultimately this part of the process will depend on

the skill and knowledge of the individual analyst; two different experts may pick different sets of “similar” firms, and thus generate different values from their relative valuation analysis.

BASIC PRINCIPLES OF RELATIVE VALUATION

Analysis based on relative valuation requires the analyst to choose a suitable universe of companies that are more or less comparable with one another. There is no standardized approach concerning how to choose such a universe of similar firms, and the process relies to some extent on an analyst’s personal judgment concerning the particular industry and geography involved. However, it is possible to lay out some general principles that combine practitioners’ insights with the results of academic inquiry.

Sources of Data

Relative valuation approaches can only be employed if there is sufficient information, produced on an approximately consistent footing, about the various companies that are the subjects of analysis. In most countries, companies that are publicly listed on stock exchanges are required by law and regulation to report their historical results publicly in a timely manner, or risk being delisted from the exchange. (There may be occasional exceptions to this general pattern, particularly for entities that are majority owned or controlled by their home country government. But such anomalies are not frequently observed except during crisis periods.) Consequently, it is almost always possible to obtain information about listed companies’ historical results. However, multiples based solely on historical data may not provide a complete picture, as most analysts would probably agree that forward-looking estimates are likely to provide more useful insights into the market’s opinion of a particular company (Valentine, 2011, p. 261).

Investment banks, rating agencies, and other firms can provide estimates of a firm’s future

earnings, revenues, and other metrics, typically over the next two or three years. Various data providers such as Bloomberg or Thomson Reuters collect such information and use it as the basis for “consensus” estimates, which can be viewed as representing the market’s general opinion of a company’s future prospects. It is also possible to use a firm’s own in-house estimates for the companies under coverage, as these may incorporate insights that are not yet reflected in current pricing. However, for precisely this reason, in-house estimates should be used as a supplement rather than as a replacement for consensus figures.

It is conventional to consider more than one year of data, as there may be disparities in how the market is valuing results in the immediate future and in the slightly longer term. However, it is often difficult or impossible to obtain consensus estimates more than two or three years into the future. Consequently, relative valuation approaches generally focus on relatively short periods into the future, rather than seeking to gauge how the market is valuing expected performance five or ten years hence. (In this respect, relative valuation analysis can be viewed as somewhat limited by comparison with DCF approaches, which typically give considerably more attention to the relatively distant future.)

Number of Comparable Firms

In general, an analyst would like to use data from other firms that are as similar as possible. However, if the criteria for “similarity” are specified too stringently, then there may be too few firms included in the universe. And if the sample is too small, then the idiosyncrasies of individual firms may exert an excessive influence on the average multiple, even if the analyst focuses on the median rather than the mean when calculating the “average” multiple.

Generally speaking, we believe that it is desirable to have at least five or six comparable companies, in order to begin drawing conclusions about relative valuation for a particular indus-

try. Conversely, there may be few benefits from considering more than 12 companies, particularly if the larger universe contains firms that resemble less closely the particular company that is the focus of the analyst’s attention.¹ For most practical purposes, a group of between six and 12 comparable firms should be sufficiently large to produce usable results.

Basis for Selecting Comparable Firms

In an ideal situation, a universe of comparable companies would be similar in terms of size, industry focus, and geography. This tends to be easier when considering small or mid-sized firms—say, with market caps between \$100 million and \$10 billion (based on 2010 U.S. dollars). Firms that are below this size limit, in other words microcap stocks, may be more difficult to use for relative valuation purposes. Even if these firms are public, they may receive less coverage from research analysts, who typically are more interested in companies that are large, liquid, and already owned by institutional investors (see Bhushan, 1989).

Conversely, it can also be difficult to perform relative value analysis on companies with relatively high market capitalization. Many large firms are dominant players in their particular market niches, in which case they may be more likely to trade at a premium reflecting their higher degree of market power. Alternatively, large firms may be effectively a conglomerate of numerous smaller entities, each engaged in a specific activity, and there may be no other large or small firm that produces an approximately equivalent blend of goods and/or services.

When attempting to assess the relative value of firms that are large and/or complex, it can often be useful to assess “relative value” using two separate approaches. The first approach is to consider the firm as a complete entity and try to find other firms that are at least somewhat comparable in terms of size and complexity, even if their business mix is not precisely identical. In such cases, it can often be useful

to consider similar firms that may be located in other countries, even though their different geographical positioning may affect their level of risk and thus the multiples at which they trade. The second approach is to use a sum-of-the-parts valuation method, which will be discussed in more detail later in this entry.

Geography and Clientele

Differences related to geographic location can affect the extent to which companies can be viewed as broadly similar. For instance, in the United States public utilities are predominantly regulated at the state level, and the public utility commissions in one state may operate quite differently from their counterparts elsewhere. Consequently, a public utility operating in one state may not be directly comparable with a public utility located in another state. In recent decades, there has been a wave of acquisition activity in the U.S. utility industry, so that now some utilities have operations in multiple states. In such instances, the valuation placed on a utility will presumably incorporate investors' perceptions of the regulatory environment affecting each of its state-level operations. For relative value purposes, a group of multistate public utilities may not be very similar to a public utility that is operating in only one state.

Regional differences in regulatory regimes may only affect a subset of companies. However, firms in the same industry may well have quite different client bases and geographic exposures. For instance, one retailer may aim to sell a wide range of goods to a mass-market client base at the regional or national level, while another retailer might instead focus on selling a limited number of luxury products to the most affluent members of the global population. These two firms are likely to have substantially different product quality, cost bases, profit margins, and sensitivity to macroeconomic conditions. In particular, retailers of luxury goods to a global client base may have developed brands that transcend national borders, and a high proportion of their current and future

revenues and profits may come from outside their home country. Under such conditions, it is possible that a suitable universe of comparable companies might include at least a few foreign firms, particularly if they have similarly broad geographic reach.

In past decades, analysts focusing on U.S. firms would probably have only rarely used foreign firms in their analysis of "comparable companies." However, as both U.S. and foreign firms have become increasingly globalized, and as accounting standards around the world have gradually started to become more similar, we believe that for some types of relative value analysis, there may be benefits to including firms that are generally comparable in terms of size and product mix, even if their legal headquarters are not located in the United States. For more insights into these issues, see Copeland, Koller, and Murrin (2000, Chapter 18).

Many companies have "depository receipts" in other markets, such as ADRs. Consensus estimates may be available for a firm's local results and/or its depository receipts. The estimates for the depository receipts may be affected by actual or expected movements between the currencies of the two countries, which may bias the analysis. We therefore recommend that when calculating figures for companies that are listed in different countries, all multiples should be consistently calculated in terms of local currency throughout, in order to ensure that anticipated or historical currency fluctuations will not affect the results. A substantial number of non-US companies have a share price quoted in one currency, but report their financial results in another currency; to avoid potential mismatch-related errors in such cases, it may be prudent to convert all numbers into a single numéraire such as the US dollar.

Sector and Industry Characteristics

Some academic research has examined different ways of selecting a universe of comparable firms. Bhojraj, Lee, and Oler (2003) compared the effect of using four different industry

classification methods, and concluded that at least for a universe of U.S. securities, the Global Industry Classification Standard (jointly developed and maintained by Standard & Poor's and Morgan Stanley Capital International) appeared to do the best job of identifying firms with similar *valuation multiples* and stock price movements. Chan, Lakonishok, and Swaminathan (2007) compared the effect of using industry classification schemes with statistically based clustering approaches, and found that examining stocks in terms of industry membership seemed to give better explanatory power than working in terms of either sectors or subindustries. To our knowledge, there have not been any parallel investigations into the effectiveness of different industry classification schemes for cross-national analysis. The results of Phylaktis and Xia (2006) suggest that the importance of sector-level effects has been increasing in recent years, while the influence of country-level effects has waned slightly.

Technology and Intraindustry Diversity

As discussed above, some academic research has suggested that firms from similar industries tend to trade at similar multiples and to experience similar stock price movements. Industry membership therefore would seem to be a useful starting point for analysis. Thus, for instance, trucking companies and railroad companies both provide transportation services, but railroads will generally trade at different multiples from trucking companies because their cost structure and balance sheets tend to be quite different.

In some cases, there can be substantial variation even within a particular subindustry. For instance, "publishing" covers a wide variety of different business models, including daily newspapers, weekly magazines, publishers of textbooks and professional journals, printers of fiction or nonfiction books, and suppliers of financial data. Each of these individual industries is likely to have different sources of

revenue, different technological requirements, different cost structures, and different rates of expected growth. Admittedly, the larger publishing houses may have operations spanning several different fields, but the relative contributions of each division to the firm's overall revenues and profits may differ substantially. In such instances, relative value analysis may result in a wide range of valuation multiples, possibly with several different clusters reflecting each firm's competitive position. We consider such difficulties in the next section.

There are also some industries in which technological differences are the principal basis on which relative values are assigned. For instance, small companies in the field of biotechnology may have only a handful of products, each of which could potentially be a great success or a dismal failure. Some companies of this type may be still at the prerevenue stage when they go public, so that their valuation is entirely based on the market's expectations about the ultimate value of technology that has not yet generated actual sales. In such instances, relative value analysis might require particularly careful selection of companies that are truly comparable in terms of the market's perception of their stage of development and the likelihood that their key products will ultimately be successful. Arguably, relative value analysis in such cases may not generate particularly useful results, because the spread of potential outcomes is so broad.

Bimodal and Multimodal Patterns

Sometimes the outcome of a relative value analysis will show that the valuation multiples are not evenly spread between low and high, but instead are bimodal or multimodal—in other words, there seem to be two or more clusters of results. We show an example of this in our hypothetical example below, which suggests that in a universe of seven firms, two are expected to achieve a return on equity (ROE) of 11% to 12% in FY0 and FY1, whereas the other companies are generally projected to deliver an

ROE of 8% to 9%. Such differences may appear relatively minor, but if the market really does expect these outcomes, then the two companies with higher profitability may legitimately be expected to trade at a premium to their peers.

When a relative valuation table appears to have bimodal or multimodal characteristics, an analyst will generally be well advised to investigate further. In any given sector or industry, there may well be some firms that are truly capable of producing higher returns than their peers, perhaps as a result of better management, a stronger market position, or a more supportive regulatory environment. Relative valuation methods can identify potential outliers of this type, but cannot test whether the estimates themselves are reasonable.

One potentially useful approach is to extend the analysis further back into the past, using historical prices for valuation purposes, and if possible also using as-was projections for the relevant period. Such projections are now widely available from various different data vendors, including Bloomberg, FactSet, and Thomson Reuters. Consider the companies that are currently trading at a premium or a discount to their peers—did they also trade at a discount to their peers in the past? A logical extension of relative value analysis based on a single period is to gauge whether a particular firm persistently tends to trade at a lower or higher multiple than its peers, and then assess whether its current multiple is above or below what would be expected on the basis of prior periods. Damodaran (2006, Chapter 7, p. 244) notes that relative valuations frequently have low persistence over time. For industries in which this is the case, then relative valuation methods may indeed provide useful investment signals.

Choice of Valuation Multiples

Many relative valuation methods compare a company's share price with some measure of its performance, such as earnings per share (EPS) or free cash flow per share. Other relative val-

uation methods compare a company's share price with some measure of its size, such as book value per share. Block (1999) has reported that the majority of practitioners consider that when analyzing securities, measures of earnings and cash flow are somewhat more important than measures of book value or dividends. However, many practitioners will make use of various metrics in their work, in the expectation that the different multiples will provide varying perspectives. Liu, Nissim, and Thomas (2002) compared the efficacy of six different metrics for relative valuations of U.S. firms on a universe-wide basis. Liu, Nissim, and Thomas (2007) extended the analysis to seven different metrics applied to 10 different countries and multiple industries. Hooke (2010, Chapter 15) presents an example using eight different metrics applied to the single industry of temporary staffing companies. In a hypothetical example below, we use three different metrics for relative valuation analysis, and we believe that most practitioners would consider that between three and six different metrics is probably justifiable. It is certainly possible to have a much larger number of metrics (see Damodaran, 2006, p. 650), but the results may be harder to interpret.

A ratio such as price/earnings can be calculated in terms of share price/EPS, or alternatively can be interpreted as market cap/net income. For most purposes, these two ratios will be the same. However, share issuance or buyback activity may impair the comparability of figures expressed in terms of EPS. If there is any possibility of ambiguity, then we would generally recommend using market cap/net income.

For instance, a company may currently have 100 million shares outstanding, a current share price of \$40, and expected earnings of \$2 in FY0 and \$3 in FY1. If the P/E ratio is calculated in terms of price/EPS, then the FY0 ratio is 20 and the FY1 ratio is 13.3. However, analysts may be expecting that the company will buy back and cancel 20% of its shares during FY1. If so,

then the projected net income in FY1 would presumably be \$240 million rather than \$300 million. If the P/E ratio is calculated using market cap and net income, then the FY1 ratio would be 16.7 rather than 13.3. This hypothetical example indicates the importance of ensuring that the denominator is being calculated on a basis that reflects the historical or projected situation for the relevant period. (An investor might consider that if a firm's management is indeed strongly committed to buying back its own shares, then this might indicate that the firm's management views the shares as being undervalued. However, such considerations would presumably be included as a qualitative overlay to the relative valuation analysis.)

Choice of Numerator: Market Cap versus Firm Value

In some instances, the choice of numerator may have a significant impact on the multiple. For instance, many analysts will use price/sales ratios for valuation purposes. However, a firm's revenues are generated from the total of its capital base, comprising both equity and debt.

Consider two companies, A and B, which both have a current market cap of \$300 million and projected annual revenues of \$600 million in FY0, so that they both have a current price/sales ratio of 2. But suppose that Company A has no outstanding borrowings, whereas Company B has net debt of \$300 million. One could argue that Company B is actually rather less attractive than Company A, as apparently it requires twice as much capital to generate the same volume of sales. In effect, analyzing the company in terms of "firm value/sales" rather than price/sales would reveal that Company B is actually making less efficient use of its capital than Company A.

There is no single definition of "firm value" that is generally accepted by all practitioners. In an ideal world, one would want to have the market value of the firm's equity capital and of the firm's debt capital. However, because

corporate bonds and bank loans typically are not traded in liquid markets, there may not be any reliable indicator of the market value of debt capital. Consequently, it is conventional to use market capitalization to estimate how investors are valuing the firm's equity capital, but then to use figures from the firm's most recent balance sheet together with the notes to the financial statements as a proxy for net debt. The broadest definition of which we are aware is the following:

$$\begin{aligned} \text{Net Debt} &= \text{Total Short-Term Debt} \\ &+ \text{Total Long-Term Debt} + \text{Minority Interest} \\ &+ \text{Unfunded Pension Liabilities} \\ &- \text{Cash and Equivalents} \end{aligned}$$

In practice, for most firms, the biggest components of net debt are likely to be total short-term debt, total long-term debt, and cash and equivalents. In most cases, using an alternative definition of firm value will often have only a small impact on the calculated multiple.

Conceptually, it is possible to divide the income statement between the line items that are generated on the basis of total capital, and those that pertain solely to equity capital. For most firms, the separator between these two categories is Net Interest Expense or Net Interest Income. Analyzing relative valuation for banks and insurance companies can be somewhat more complex, as discussed in Copeland, Koller, and Murrin (2000, Chapters 21 and 22). Generally speaking, it is usually desirable that the numerator and denominator of a valuation metric should be consistent with each other (Damodaran, 2006, pp. 239–240).

Industry-Specific Multiples

Analysts covering some industries may make use of information specific to that industry, such as paid miles flown for airlines, same-store sales for retailers, or revenue per available room for hotel chains. Such data can provide insights into how the market is valuing individual

firms' historical or expected operating performance. However, we consider that they should be viewed as a supplement to other multiples, rather than as a replacement for them, for two reasons: because it can be difficult to reconcile a company's operating performance with its financial results, and also because there may be little or no intuition about what would be a "reasonable" estimate for long-run valuation levels (Damodaran, 2006, Chapter 7, pp. 237–238). Natural resource producers tend to be valued in terms of both their operating efficiency and the resources that they control, so it may be useful to include some measure of their reserves in the analysis (Hooke, 2010, Chapter 21). Many practitioners make use of efficiency metrics when using relative valuation approaches to assess some types of banks and other lending institutions (Hooke, 2010, Chapter 22).

HYPOTHETICAL EXAMPLE

Suppose that an analyst is seeking to gauge whether Company A is attractive or unattractive on the basis of relative valuation methods. Suppose that the analyst has determined that there are six other listed companies in the same

industry which are approximately the same size, and which are also comparable in terms of product mix, client base, and geographical focus.² Based on this information, the analyst can calculate some potentially useful multiples for all seven companies. A hypothetical table of such results is shown in Table 1. (For the purposes of this simple hypothetical example, we are assuming that all the firms have the same fiscal year. We will consider calendarization later in this entry.)

In this hypothetical scenario, Company A is being compared to Companies B through G, and therefore Company A should be excluded from the calculation of median and standard deviation, which would otherwise lead to double-counting. The median is used because it tends to be less influenced by outliers than the statistical mean, so it is likely to be a better estimate for the central tendency. (Similarly, the standard deviation can be strongly influenced by outliers, and it would be possible to use "median absolute deviation" as a more robust way of gauging the spread around the central tendency. Such approaches may be particularly appropriate when the data contain one or a handful of extreme outliers for certain metrics, which might be associated with company-specific idiosyncrasies.) The table has been arranged in terms of market

Table 1 Hypothetical Relative Valuation Results

Company	Share Price (\$)	Market Cap (\$m)	P/E		P/FCF		P/B	
			FY0	FY1	FY0	FY1	FY0	FY1
A	20.00	400	12.0	10.0	8.5	7.0	1.30	1.20
B	16.00	550	11.5	11.5	5.0	6.0	1.00	0.95
C	40.00	500	13.0	12.0	8.0	7.5	1.50	1.40
D	15.00	450	12.5	12.0	8.0	7.0	1.10	1.05
E	13.00	350	14.5	13.0	9.0	8.0	1.25	1.15
F	30.00	350	12.5	12.5	7.0	4.5	1.15	1.15
G	15.00	300	15.0	14.0	7.0	6.0	1.20	1.15
Median		400	12.75	12.25	7.50	6.50	1.18	1.15
Std Dev		98.3	1.33	0.89	1.37	1.26	0.17	0.15
<i>A versus Median</i>		0%	−6%	−18%	13%	8%	11%	4%

Notes: P/E refers to price/earnings before extraordinary items; P/B refers to price / book value; P/FCF refers to price/free cash flow (defined as earnings before extraordinary items plus noncash items taken from the cash flow statement); FY0 refers to the current fiscal year; FY1 refers to the next fiscal year; figures for FY0 and FY1 could have been derived from consensus sell-side estimates or other sources.

cap, from largest to smallest, which can sometimes reveal patterns associated with larger or smaller firms, though there don't appear to be any particularly obvious trends in this particular set of hypothetical numbers.

The table suggests that the chosen universe of comparable companies may be reasonably similar to Company A in several important respects. In terms of size, Companies B, C, and D are slightly larger, while Companies E, F, and G are slightly smaller, but the median market cap across the six firms is the same as Company A's current valuation. In terms of P/E ratios, Company A looks slightly cheap in terms of FY0 earnings and somewhat cheaper in terms of FY1 earnings. In terms of P/FCF ratios, Company A looks somewhat expensive in terms of FY0 free cash flow, but only slightly expensive in terms of FY1 free cash flow. And finally, in terms of P/B ratios, Company A looks somewhat expensive in terms of FY0 book value, but roughly in line with its peers in terms of FY1 book value.

Analysis of the Hypothetical Example

So what are the implications of these results? First, Company A looks relatively cheap compared to its peer group in terms of P/E ratios, particularly in terms of its FY1 multiples. Second, Company A looks rather expensive compared to its peer group in terms of P/FCF and P/B ratios, particularly in terms of FY0 figures. If an analyst were focusing solely on P/E, then Company A would look cheap compared with the peer group, and this might suggest that Company A could be an attractive investment opportunity.

However, the analyst might be concerned that Company A looks comparatively cheap in terms of P/E, but somewhat expensive in terms of price/book. One way to investigate this apparent anomaly is to focus on ROE, which is defined as earnings/book value. Using the data in the table, it is possible to calculate the ROE

for Company A and for the other six companies by dividing the P/B ratio by the P/E ratio—because this effectively cancels out the “price” components, and thus will generate an estimated value for EPS divided by book value per share, which is one way to calculate ROE.

The results suggest that Company A is expected to deliver an ROE of 10.8% in FY0 and 12% in FY1, whereas the median ROE of the other six firms is 8.7% in FY0 and 8.8% in FY1. Most of the comparable companies are expected to achieve an ROE of between 8% and 9% in both FY0 and FY1, though apparently Company C is expected to achieve an ROE of 11.5% in FY0 and 11.7% in FY1. (A similar analysis can be conducted using “free cash flow to equity,” which involves dividing the P/B ratio by the P/FCF ratio. This indicates that Company A is slightly below the median of Companies B through G in FY0, but in line with its six peers during FY1.)

These results suggest that Company A is expected to deliver an ROE that is substantially higher than most of its peers. Suppose that an analyst is skeptical that Company A really can deliver such a strong performance, and instead hypothesizes that Company A's ROE during FY0 and FY1 may only be in line with the median ROE for the peer group in each year. Based on the figures in Table 1, Company A's book value in FY0 is expected to be \$15.38, and the company is projected to deliver \$1.67 of earnings. Now suppose that Company A's book value remains the same, but that its ROE during FY0 is only 8.7%, which is equal to the median for its peers. Then the implied earnings during FY0 would only be \$1.35, and the “true” P/E for Company A in FY0 would be 14.9, well above the peer median of 12.75.

The analysis can be extended a little further, from FY0 to FY1. The figures in the table above suggest that Company A's book value in FY1 will be \$16.67, and that the company will generate \$2.00 of earnings during FY1. But if Company A only produced \$1.35 of earnings during FY0, rather than the table's expectation of \$1.67, then the projected FY1 book value may be too

high. A quick way to estimate Company A's book value in FY1 is to use a *clean surplus* analysis, using the following equation:

$$\text{Book}_{\text{FY1}} = \text{Book}_{\text{FY0}} + \text{Net Income}_{\text{FY1}} \\ - \text{Dividends}_{\text{FY1}}$$

Based on the figures in the table above, Company A is expected to have earnings of \$1.67 during FY0, and \$2.00 during FY1. The implied book value per share is \$15.38 in FY0, and \$16.67 during FY1. According to the clean surplus formula, Company A is expected to pay a dividend of \$0.38 per share in FY1.

Assuming that the true earnings in FY0 are indeed \$1.35 rather than \$1.67, and that the dividend payable in FY1 is still \$0.38, then the expected book value for Company A in FY1 would be \$16.35 rather than \$16.67. Taking this figure and applying the median FY1 peer ROE, the expected FY1 earnings for Company A would be \$1.42 rather than \$2.00, and consequently the "true" P/E for FY1 would be 13.9 instead of the figure of 10.0 shown in the table. At those levels, the stock would presumably no longer appear cheap by comparison with its peer group. Indeed, Company A's FY1 P/E multiple would be roughly in line with Company G, which has the highest FY1 P/E multiple among the comparable companies.

This quick analysis therefore suggests that the analyst may want to focus on why Company A is expected to deliver FY0 and FY1 ROE that is at or close to the top of its peer group. As noted previously, Company A and Company C are apparently expected to have an ROE that is substantially stronger than those of the other comparable companies. Is there something special about Companies A and C that would justify such an expectation? Conversely, is it possible that the estimates for Companies A and C are reasonable, but that the projected ROE for the other companies is too pessimistic? If the latter scenario is valid, then it's possible that the P/E ratios for some of the other companies in the comparable universe are too high, and thus

that those firms could be attractively valued at current levels.

Other Potential Issues

Multiples Involving Low or Negative Numbers

It is conventional to calculate valuation multiples with the market valuation as the numerator and the firms' financial or operating data as the denominator. If the denominator is close to zero, or negative, then the valuation multiple may be very large or negative. The simplest example of such problems might involve a company's earnings. Consider a company with a share price of \$10 and projected earnings of \$0.10 for next year. Such a company is effectively trading at a P/E of 100. If consensus estimates turn more bearish, and the company's earnings next year are expected to be minus \$0.05, the company will now be trading at a P/E of -200.

It is also possible for a firm to have negative shareholders' equity, which would indicate that the total value of its liabilities exceeds the value of its assets. According to a normal understanding of accounting data, this would indicate that the company is insolvent. However, some companies have been able to continue operating under such circumstances and even to retain a stock exchange listing. Firms with negative shareholders' equity will also have a negative price/book multiple. (In principle, a firm can even report negative net revenues during a particular period, though this would require some rather unusual circumstances. One would normally expect few firms to report negative revenues for more than a single quarter.)

As noted previously, averages and standard deviations tend to be rather sensitive to outliers, which is one reason to favor using the median and the median absolute deviation instead. But during economic recessions at the national or global level, many companies may have low or negative earnings. Similarly, firms in cyclical industries will often go through

periods when sales or profits are unusually low, by comparison with their average levels through a complete business cycle. Under such circumstances, an analyst may prefer not to focus on conventional metrics such as Price/Earnings, but instead to use line items from higher up the income statement that typically will be less likely to generate negative numbers.

Calendarization

Some of the firms involved in the relative valuation analysis may have fiscal years that end in different months. Most analyst estimates are based on a firm's own reporting cycle. It is usually desirable to ensure that all valuation multiples are being calculated on a consistent basis, so that calendar-based effects are not driving the analysis.

One way to ensure that all valuation multiples are directly comparable is to calendarize the figures. Consider a situation where at the start of January, an analyst is creating a valuation analysis for one firm whose fiscal year ends in June, while the other firms in the universe have fiscal years that end in December. Calendarizing the results for the June-end firm will require taking half of the projected number for FY0 and adding half of the projected number for FY1. (If quarter-by-quarter estimates are available, then more precise adjustments can be implemented by combining 3QFY0, 4QFY0, 1QFY1, and 2QFY1.)

Calendarization is conceptually simple, but may require some care in implementation during the course of a year. One would expect that after a company has reported results for a full fiscal year, the year defined as "FY0" would immediately shift forward 12 months. However, analysts and data aggregators may not change the definitions of "FY0" and "FY1" for a few days or weeks. In case of doubt, it may be worth looking at individual estimates in order to double-check that the correct set of numbers is being used.

Sum-of-the-Parts Analysis

When attempting to use relative valuation methods on firms with multiple lines of business, the analyst may not be able to identify any company that is directly similar on all dimensions. In such instances, relative valuation methods can be extended to encompass "sum-of-the-parts" analysis, which considers each part of a business separately and attempts to value them individually by reference to companies that are mainly or solely in one particular line of business (see Hooke, 2010, Chapter 18).

Relative valuation analysis based on sum-of-the-parts approaches will involve the same challenges as were described above—identifying a suitable universe of companies engaged in each particular industry, collecting and collating the necessary data, and then using the results to gauge what might be a "fair value" for each of the individual lines of business. But in addition to these considerations, there is an additional difficulty, which is specific to sum-of-the-parts analysis. This problem is whether to apply a *conglomerate discount*, and if so, how much.

Much financial theory assumes that all else equal, investors are likely to prefer to invest in companies that are engaged in a single line of business, rather than to invest in conglomerates that have operations across multiple industries. Investing in a conglomerate effectively means being exposed to all of that conglomerate's operations, and the overall mix of industry exposures might not mimic the portfolio that the investor would have chosen if it were possible instead to put money into individual companies.

A possible counterargument might be that a conglomerate with strong and decisive central control may achieve *synergies* with regard to revenues, costs, or taxation that would not be available to individual free-standing firms dealing at arms' length with one another. A skeptical investor might wonder, on the other hand, about whether the potential positive impact of such synergies may be partly or wholly

undermined by the negative impacts of centralized decision making, transfer pricing, and regulatory or reputational risk.

For these reasons, an analyst might consider that it is reasonable to apply a discount to the overall value that emerges from the “sum of the parts.” Some practitioners favor a discount of somewhere between 5% and 15%, for the reasons given above. Academic research on spinoffs has suggested that the combined value of the surviving entity and the spun-off firm tends to rise by an average of around 6%, though with a wide range of variation (see Burch and Nanda, 2003). (Some analysts have suggested that in some particular contexts, for instance in markets where competent managers are very scarce, then investors should be willing to pay a premium for being able to invest in a conglomerate that is fortunate enough to have such executives. However, this appears not to be a mainstream view.)

Relative Valuation versus DCF: A Comparison

Relative valuation methods can generally be implemented fairly fast, and the underlying information necessary to calculate can also be updated quickly. Even with the various complexities discussed above, an experienced analyst can usually create a relative valuation table within an hour or two. And the calculated valuation multiples can adjust as market conditions and relative prices change. In both respects, relative valuation methods have an advantage over DCF models, which may require hours or days of work to build or update, and which require the analyst to provide multiple judgment-based inputs about unknowable future events. Moreover, as noted by Baker and Ruback (1999), if a DCF model is extended to encompass multiple possible scenarios, it may end up generating a range of “fair value” prices that is too wide to provide much insight into whether the potential investment is attractive at its current valuation.

Relative valuation methods focus on how much a company is worth to a minority shareholder, in other words an investor who will have limited or zero ability to influence the company’s management or its strategy. Such an approach is suitable for investors who intend to purchase only a small percentage of the company’s shares and to hold those shares until the valuation multiple moves from being “cheap” to being “in line” or “expensive” compared with the peer group. As noted above, relative valuation methods make no attempt to determine what is the “correct” price for a company’s shares, but instead focus on trying to determine whether a company looks attractive or unattractive by comparison with other firms that appear to be approximately similar in terms of size, geography, industry, and other parameters.

DCF methods attempt to determine how much a company is worth in terms of “fair value” over a long time horizon. DCF methods can readily incorporate a range of assumptions about decisions in the near future or the distant future, and therefore can provide a range of different scenarios. For this reason, most academics and practitioners consider that DCF methods are likely to produce greater insight than relative valuation methods into the various forces that may affect the fair value for a business. More specifically, DCF methods can be more applicable to situations where an investor will seek to influence a company’s future direction—perhaps as an activist investor pushing management in new directions, or possibly as a bidder for a controlling stake in the firm. In such situations, relative valuation analysis is unlikely to provide much insight because the investor will actually be seeking to affect the company’s valuation multiples directly, by affecting the value of the denominator.

Nevertheless, even where an analyst favors the use of DCF approaches, we consider that relative valuation methods can still be valuable as a “sanity check” on the output from a DCF-based valuation. An analyst can take the

expected valuation from the DCF model and compare it with the projected values for net income, shareholders' equity, operating cash flow, and similar metrics. These ratios drawn from the DCF modeling process can then be compared with the multiples for a universe of similar firms. If the multiples generated by the analyst's DCF model are approximately comparable with the multiples that can be derived for similar companies that are already being publicly traded, then the analyst may conclude that the DCF model's assumptions appear to be reasonable. However, if the multiples from the analyst's model appear to diverge considerably from the available information concerning valuation multiples for apparently similar firms, then it may be a good idea to reexamine the model, rechecking whether the underlying assumptions are truly justifiable.

Relative valuation methods can also be useful in another way when constructing DCF models. Most DCF models include a "terminal value," which represents the expected future value of the business, discounted back to the present, from all periods subsequent to the ones for which the analyst has developed explicit estimates. One way to calculate this terminal value is in terms of a perpetual growth rate, but the choice of a particular growth rate can be difficult to justify on the basis of the firm's current characteristics. An alternative approach is to take current valuation multiples for similar firms and use those values as multiples for terminal value (see Damodaran, 2006, Chapter 4, pp. 143–144).

KEY POINTS

- Relative valuation methods tend to receive less attention from academics than DCF approaches, but such methods are widely used by practitioners. If relative valuation approaches suggest that a company is cheap on some metrics but expensive on others, this may indicate that the market views that com-

pany as being an outlier for some reason, and an analyst will probably want to investigate further.

- Choosing an appropriate group of comparable companies is perhaps the most challenging aspect of relative valuation analysis. Where possible, an analyst should seek to identify six to 12 companies that are similar in terms of size, geography, and industry. If this is not possible, then an analyst should feel free to relax one or more of these parameters in order to obtain a usable universe.
- Determining an appropriate set of valuation multiples is also important. Calculating a single set of multiples is likely to provide fewer insights than using several different metrics that span multiple time periods. It is conventional to use consensus estimates of future financial and operating performance, as these presumably represent the market's collective opinion of each firm's prospects.
- Most relative valuation analysis is performed using standard multiples such as price/earnings or firm value/sales. Under some conditions, using industry-specific multiples can be valuable, though there may be fewer consensus estimates for such data, and there may also be less intuition about what is the "fair" price for such ratios.
- Relative valuation methods are particularly useful for investors who aim to take minority stakes in individual companies when they are "cheap" relative to their peers, and then sell those stakes when the companies become "expensive." Such methods are likely to be less directly useful for investors who will seek to influence a company's management, or who aim to take a controlling stake in a company. For such investors, DCF methods are likely to be more applicable.

NOTES

1. By contrast, in an example of how to assess a small wine producer, the proposed universe of comparables consisted of 15 "beverage

firms," including both small and large caps, and covering specialists in beer, wine, and soft drink production. Arguably, some of these are unlikely to be very similar to the proposed target of analysis. See Chapter 7 in Damodaran (2006, pp. 249–252).

2. For further examples using real firms and actual figures, see Damodaran (2006, Chapters 7 and 8) or Hooke (2010, Chapter 15).

Equity Analysis in a Complex Market

BRUCE I. JACOBS, PhD

Principal, Jacobs Levy Equity Management

KENNETH N. LEVY, CFA

Principal, Jacobs Levy Equity Management

Abstract: Investment approaches are determined by investors' views of the market. For investors who believe the market is basically efficient, so that price changes are essentially random and unpredictable, the reasonable approach is passive investing, or indexing, which makes no attempt to outperform the underlying market. Investors who believe there are clear-cut patterns discernible in stock price movements may aim for above-market returns by using fairly simple approaches, such as buying stocks with low price/earning ratios or buying small-capitalization stocks. But what if the market is not totally efficient, but there are no simple patterns that can be exploited for consistent excess returns? Such a complex market requires an investment approach capable of dealing with that complexity.

Scientists classify systems into three types—ordered, random, and complex. Ordered systems, such as the structure of diamond crystals or the dynamics of pendulums, are definable and predictable by relatively simple rules and can be modeled using a relatively small number of variables. Random systems like the Brownian motion of gas molecules or white noise (static) are unordered; they are the product of a large number of variables. Their behavior cannot be modeled and is inherently unpredictable.

Complex systems like the weather and the workings of DNA fall somewhere between the domains of order and randomness. Their behavior can be at least partly comprehended and modeled, but only with great difficulty. The number of variables that must be modeled and

their interactions are beyond the capacity of the human mind alone. Only with the aid of advanced computational science can the mysteries of complex systems be unraveled.¹

The stock market is a complex system.² Stock prices are not completely random, as the efficient market hypothesis and random walk theory would have it. Some price movements can be predicted, and with some consistency. But stock price behavior is not ordered. It cannot be successfully modeled by simple rules or screens such as low price-to-earnings ratios (P/Es) or even by elegant theories such as the capital asset pricing model or arbitrage pricing theory. Rather, stock price behavior is permeated by a complex web of *interrelated return effects*. A model of the market that is complex enough to

disentangle these effects provides opportunities for modeling price behavior and predicting returns.

This entry describes our approach to *investing* and its application to the *stock selection*, *portfolio construction*, and performance evaluation problems. We begin with the very basic question of how one should approach the *equity market*. Should one attempt to cover the broadest possible range of stocks, or can greater analytical insights be garnered by focusing on a particular subset of the market or a limited number of stocks? Each approach has its advantages and disadvantages. However, combining the two may offer the best promise of finding the key to unlocking investment opportunity in a complex market.

While covering the broadest possible range of stocks, a complex approach recognizes that there are significant differences in the ways different types of stocks respond to changes in both fundamentals and investor behavior. This requires taking into account the interrelationships between numerous potential sources of price behavior. *Multivariate analysis* disentangles the web of return-predictor relationships that constitutes a *complex market* and provides independent, additive return predictions that are more robust than the predictions from univariate analyses.

AN INTEGRATED APPROACH TO A SEGMENTED MARKET

While one might think that U.S. equity markets are fluid and fully integrated, in reality there are barriers to the free flow of capital. Some of these barriers are self-imposed by investors. Others are imposed by regulatory and tax authorities or by client guidelines.

Some funds, for example, are prohibited by regulation or internal policy guidelines from buying certain types of stock—non-dividend-paying stock, or stock below a given capitaliza-

tion level. Tax laws, too, may effectively lock investors into positions they would otherwise trade. Such barriers to the free flow of capital foster market segmentation.

Other barriers are self-imposed. Traditionally, for example, managers have focused (whether by design or default) on distinct approaches to stock selection. Value managers have concentrated on buying stocks selling at prices perceived to be low relative to the company's assets or earnings. Growth managers have sought stocks with above-average earnings growth not fully reflected in price. Small-capitalization managers have searched for opportunity in stocks that have been overlooked by most investors. The stocks that constitute the natural selection pools for these managers tend to group into distinct market segments.

Client preferences encourage this balkanization of the market. Some investors, for example, prefer to buy *value stocks*, while others seek *growth stocks*; some invest in both, but hire separate managers for each segment. Both institutional and individual investors generally demonstrate a reluctance to upset the apple cart by changing allocations to previously selected style managers. Several periods of underperformance, however, may undermine this loyalty and motivate a flow of capital from one segment of the market to another (often just as the out-of-favor segment begins to benefit from a reversion of returns back up to their historical mean).

The actions of investment consultants have formalized a market segmented into style groupings. Consultants design style indexes that define the constituent stocks of these segments and define managers in terms of their proclivity for one segment or another. As a manager's performance is measured against the given style index, managers who stray too far from index territory are taking on extra risk. Consequently, managers tend to stick close to their style homes, reinforcing market segmentation.

An investment approach that focuses on individual market segments can have its advantages. Such an approach recognizes, for example, that the U.S. equity market is neither entirely homogeneous nor entirely heterogeneous. All stocks do not react alike to a given impetus, but nor does each stock exhibit its own, totally idiosyncratic price behavior. Rather, stocks within a given style, or sector, or industry tend to behave similarly to each other and somewhat differently from stocks outside their group.

An approach to stock selection that specializes in one market segment can optimize the application of talent and maximize the potential for outperformance. This is most likely true for traditional, fundamental analysis. The in-depth, labor-intensive research undertaken by traditional analysts can become positively ungainly without some focusing lens.

An investment approach that focuses on the individual segments of the market, however, presents some theoretical and practical problems. Such an approach may be especially disadvantaged when it ignores the many forces that work to integrate, rather than segment, the market.

Many managers, for example, do not specialize in a particular market segment but are free to choose the most attractive securities from a broad universe of stocks. Others, such as style rotators, may focus on a particular type of stock, given current economic conditions, but be poised to change their focus should conditions change. Such managers make for capital flows and price arbitrage across the boundaries of particular segments.

Furthermore, all stocks can be defined by the same fundamental parameters—by market capitalization, P/E, dividend discount model ranking, and so on. All stocks can be found at some level on the continuum of values for each parameter. Thus, growth and value stocks inhabit the opposite ends of the continuums of P/E and

dividend yield, and small and large stocks the opposite ends of the continuums of firm capitalization and analyst coverage.

As the values of the parameters for any individual stock change, so too does the stock's position on the continuum. An out-of-favor growth stock may slip into value territory. A small-cap company may grow into the large-cap range.

Finally, while the values of these parameters vary across stocks belonging to different market segments—different styles, sectors, and industries—and while investors may favor certain values—low P/E, say, in preference to high P/E—arbitrage tends to counterbalance too pronounced a predilection on the part of investors for any one set of values. In equilibrium, all stocks must be owned. If too many investors want low P/E, low-P/E stocks will be bid up to higher P/E levels, and some investors will step in to sell them and buy other stocks deserving of higher P/Es. Arbitrage works toward market integration and a single pricing mechanism.

A market that is neither completely segmented nor completely integrated is a complex market. A complex market calls for an investment approach that is 180 degrees removed from the narrow, segment-oriented focus of traditional management. It requires a complex, *unified approach* that takes into account the behavior of stocks across the broadest possible selection universe, without losing sight of the significant differences in price behavior that distinguish particular market segments.

Such an approach offers three major advantages. First, it provides a coherent evaluation framework. Second, it can benefit from all the insights to be garnered from a wide and diverse range of securities. Third, because it has both breadth of coverage and depth of analysis, it is poised to take advantage of more profit opportunities than a more narrowly defined, segmented approach proffers.

A Coherent Framework

To the extent that the market is integrated, an investment approach that models each industry or style segment as if it were a universe unto itself is not the best approach. Consider, for example, a firm that offers both core and value strategies. Suppose the firm runs a model on its total universe of, say, 3,000 stocks. It then runs the same model or a different, segment-specific model on a 500-stock subset of large-cap value stocks.

If different models are used for each strategy, the results will differ. Even if the same model is estimated separately for each strategy, its results will differ because the model coefficients are bound to differ between the broader universe and the narrower segment. What if the core model predicts GM will outperform Ford, while the value model shows the reverse? Should the investor start the day with multiple estimates of one stock's alpha? This would violate what we call the *law of one alpha*.³

Of course, the firm could ensure coherence by using separate models for each market segment—growth, value, small-cap, linking the results via a single, overarching model that relates all the subsets. But the firm then runs into a second problem with segmented investment approaches: To the extent that the market is integrated, the pricing of securities in one segment may contain information relevant to pricing in other segments.

For example, within a generally well-integrated national economy, labor market conditions in the United States differ region by region. An economist attempting to model employment in the Northeast would probably consider economic expansion in the Southeast. Similarly, the investor who wants to model growth stocks should not ignore value stocks. The effects of inflation, say, on value stocks may have repercussions for growth stocks; after all, the two segments represent opposite ends of the same P/E continuum.

An investment approach that concentrates on a single market segment does not make use of

all available information. A complex, unified approach considers all the stocks in the universe, value and growth, large and small. It thus benefits from all the information to be gleaned from a broad range of stock price behavior.

Of course, an increase in breadth of inquiry will not benefit the investor if it comes at the sacrifice of depth of inquiry. A complex approach does not ignore the significant differences across different types of stock, differences exploitable by specialized investing. What's more, in examining similarities and differences across market segments, it considers numerous variables that may be considered to be defining.

For value, say, a complex approach does not confine itself to a dividend discount model measure of value, but examines also earnings, cash flow, sales, and yield value, among other attributes. Growth measurements to be considered include historical, expected, and sustainable growth, as well as the momentum and stability of earnings. Share price, volatility, and analyst coverage are among the elements to be considered along with market capitalization as measures of size.

At a deeper level of analysis, one must also consider alternative ways of specifying such fundamental variables as earnings or cash flow. Over what period does one measure earnings? If using analyst earnings expectations, which measure provides the best estimate of future real earnings? The consensus of all available estimates made over the past six months, or only the very latest earnings estimates? Are some analysts more accurate or more influential? What if a recent estimate is not available for a given company?⁴

Predictor variables are often closely correlated with each other. *Small-cap stocks*, for example, tend to have low P/Es; low P/E is correlated with high yield; both low P/E and high yield are correlated with dividend discount model (DDM) estimates of value. Furthermore, they may be correlated with a stock's industry affiliation. A simple low-P/E screen, for example, will tend to select a large number

of bank and utility stocks. Such correlations can distort naïve attempts to relate returns to potentially relevant predictors. A true picture of the return-predictor relationship emerges only after *disentangling* the predictors.

DISENTANGLING

The effects of different sources of stock return can overlap. In Figure 1, the lines represent connections documented by academic studies; they may appear like a ball of yarn after the cat got to it. To unravel the connections between predictor variables and return, it is necessary to examine all the variables simultaneously.

For instance, the low-P/E effect is widely recognized, as is the small-size effect. But stocks with low P/Es also tend to be of small size. Are P/E and size merely two ways of looking at the same effect? Or does each variable matter? Perhaps the excess returns to small-cap stocks are merely a January effect, reflecting the tendency of taxable investors to sell depressed stocks at year-end. Answering these questions requires disentangling return effects via multivariate regression.⁵

Common methods of measuring return effects (such as quintiling or univariate, single-variable, regression) are naïve because they assume, naïvely, that prices are responding only to the single variable under consideration, low

P/E, say. But a number of related variables may be affecting returns. As we have noted, small-cap stocks and banking and utility industry stocks tend to have low P/Es. A univariate regression of return on low P/E will capture, along with the effect of P/E, a great deal of noise related to firm size, industry affiliation, and other variables.

Simultaneous analysis of all relevant variables via multivariate regression takes into account and adjusts for such interrelationships. The result is the return to each variable separately, controlling for all related variables. A multivariate analysis for low P/E, for example, will provide a measure of the excess return to a portfolio that is market-like in all respects except for having a lower-than-average P/E ratio. Disentangled returns are *pure returns*.

Noise Reduction

Figure 2 plots naïve and pure cumulative monthly excess (relative to a 3,000-stock universe) returns to high book-to-price ratio (B/P). (Conceptually, naïve and pure returns come from a portfolio having a B/P that is one standard deviation above the universe mean B/P; for the pure returns, the portfolio is also constrained to have universe-average exposures to all the other variables in the model, including fundamental characteristics and industry affiliations.) The *naïve returns* show a great deal of volatility; the pure returns, by contrast, follow a much smoother path. There is a lot of noise in the naïve returns. What causes it?

Notice the divergence between the naïve and pure return series for the 12 months starting in March 1979. This date coincides with the crisis at Three Mile Island nuclear power plant. Utilities such as GPU, operator of the Three Mile Island power plant, tend to have high B/Ps, and naïve B/P measures will reflect the performance of these utilities along with the performance of other high-B/P stocks. Electric utility prices plummeted 24% after the Three Mile Island crisis. The naïve B/P measure reflects this decline.

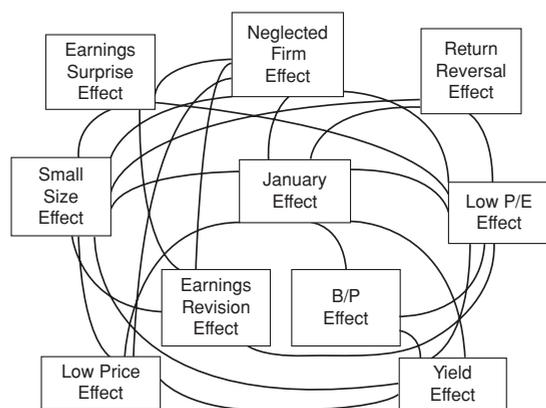

Figure 1 Return Effects Form a Tangled Web

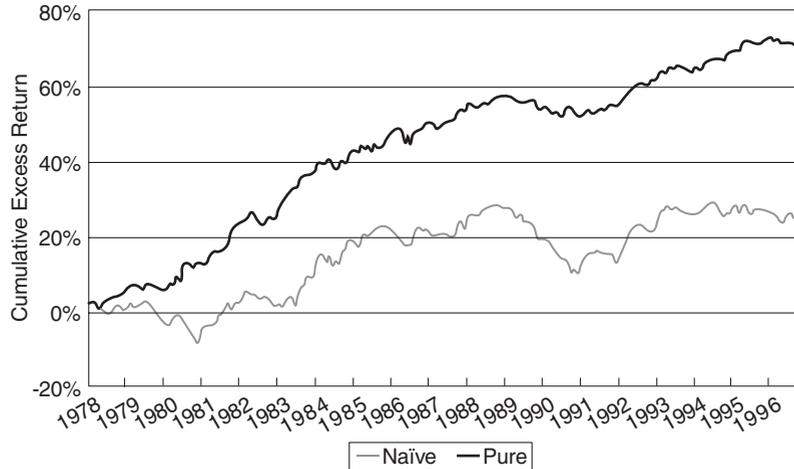

Figure 2 Naïve and Pure Returns to High Book-to-Price Ratio

But industry-related events such as Three Mile Island have no necessary bearing on the B/P variable. An investor could, for example, hold a high-B/P portfolio that does not overweight utilities, and such a portfolio would not have experienced the decline reflected in the naïve B/P measure in Figure 2. The naïve returns to B/P reflect noise from the inclusion of a utility industry effect. A pure B/P measure is not contaminated by such irrelevant variables.

Disentangling distinguishes real effects from mere proxies and thereby distinguishes between real and spurious investment opportunities. As it separates high B/P and industry affiliation, for example, it can also separate the effects of firm size from the effects of related variables. Disentangling shows that returns to small firms in January are not abnormal; the apparent January seasonal merely proxies for year-end tax-loss selling.⁶ Not all small firms will benefit from a January rebound; indiscriminately buying small firms at the turn of the year is not an optimal investment strategy. Ascertaining true causation leads to more profitable strategies.

Return Revelation

Disentangling can reveal hidden opportunities. Figure 3 plots the naïvely measured cumulative

monthly excess returns (relative to the 3,000-stock universe) to portfolios that rank lower than average in market capitalization and price per share and higher than average in terms of analyst neglect. These results derive from monthly univariate regressions. The small-cap line thus represents the cumulative excess returns to a portfolio of stocks naïvely chosen on the basis of their size, with no attempt made to control for other variables.

All three return series move together. The similarity between the small-cap and neglect series is particularly striking. This is confirmed by the correlation coefficients in the first column of Table 1. Furthermore, all series show a great deal of volatility within a broader up, down, up pattern.

Figure 4 shows the pure cumulative monthly excess returns to each size-related attribute over the period. These disentangled returns adjust for correlations not only between the three size

Table 1 Correlations Between Monthly Returns to Size-Related Variables*

Variable	Naïve	Pure
Small cap/low price	0.82	-0.12
Small cap/neglect	0.87	-0.22
Neglect/low price	0.66	-0.11

*A coefficient of 0.14 is significant at the 5% level.

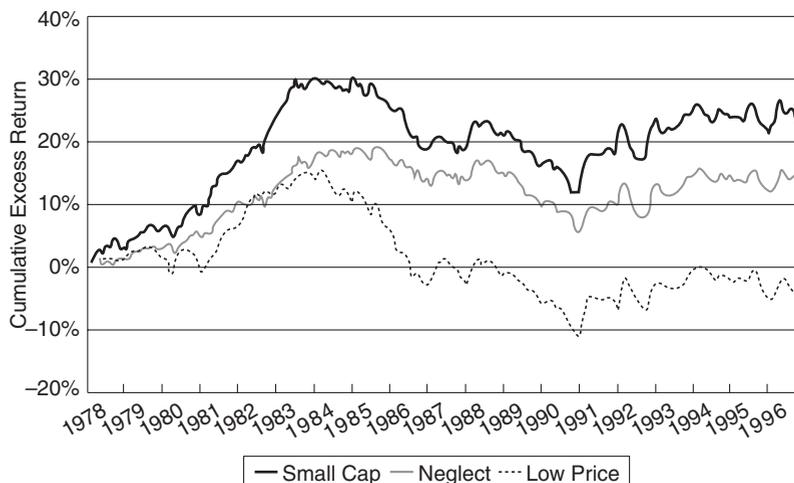

Figure 3 Naïve Returns Can Hide Opportunities (Three Size-Related Variables)

variables, but also between each size variable and industry affiliations and each variable and growth and value characteristics. Two findings are immediately apparent from Figure 4.

First, pure returns to the size variables do not appear to be nearly as closely correlated as the naïve returns displayed in Figure 3. In fact, over the second half of the period, the three return series diverge substantially. This is confirmed by the correlation coefficients in the second column of Table 1.

In particular, pure returns to small capitalization accumulate quite a gain over the pe-

riod; they are up 30%, versus an only 20% gain for the naïve returns to small cap. Purifying returns reveals a profit opportunity not apparent in the naïve returns. Furthermore, pure returns to analyst neglect amount to a substantial loss over the period. Because disentangling controls for proxy effects, and thereby avoids redundancies, these pure return effects are additive. A portfolio could have aimed for superior returns by selecting small-cap stocks with a higher-than-average analyst following (that is, a negative exposure to analyst neglect).

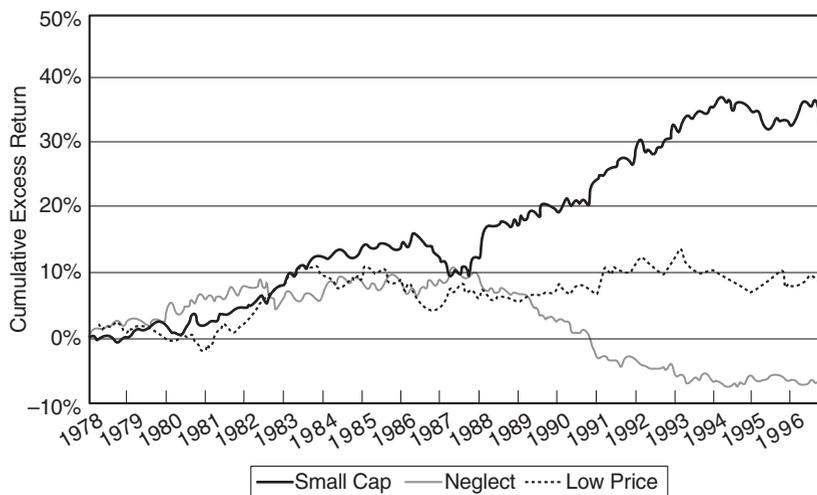

Figure 4 Pure Returns Can Reveal Opportunities (Three Size-Related Variables)

Table 2 Pure Returns Are Less Volatile, More Predictable: Standard Deviations of Monthly Returns to Size-Related Variables*

Variable	Naïve	Pure
Small cap	0.87	0.60
Neglect	0.87	0.67
Low price	1.03	0.58

*All differences between naïve and pure return standard deviations are significant at the 1% level.

Second, the pure returns appear to be much less volatile than the naïve returns. The naïve returns in Figure 3 display much month-to-month volatility within their more general trends. By contrast, the pure series in Figure 4 are much smoother and more consistent. This is confirmed by the standard deviations given in Table 2.

The pure returns in Figure 4 are smoother and more consistent than the naïve return responses in Figure 3 because the pure returns capture more signal and less noise. And because they are smoother and more consistent than naïve returns, pure returns are also more predictive.

Predictive Power

Disentangling improves the predictive power of estimated returns by providing a clearer picture of the relationships between investor behavior, fundamental variables, and macroeconomic conditions. For example, investors often prefer value stocks in bearish market environments, because growth stocks are priced more on the basis of high expectations, which get dashed in more pessimistic eras. But the success of such a strategy will depend on the variables one has chosen to define value.

Table 3 displays the results of regressing both naïve and pure monthly returns to various value-related variables on market (S&P 500) returns over the 1978–1996 period.⁷ The results indicate that DDM value is a poor indicator of a stock's ability to withstand a tide of receding market prices. The regression coeffi-

Table 3 Market Sensitivities of Monthly Returns to Value-Related Variables

Variable	Naïve	(<i>t</i> -stat.)	Pure	(<i>t</i> -stat.)
DDM	0.06	(5.4)	0.04	(5.6)
B/P	−0.10	(−6.2)	−0.01	(−0.8)
Yield	−0.08	(−7.4)	−0.03	(−3.5)

cient in the first column indicates that a portfolio with a one-standard-deviation exposure to DDM value will tend to outperform by 0.06% when the market rises by 1.00% and to underperform by a similar margin when the market falls by 1.00%. The coefficient for pure returns to DDM is similar. Whether their returns are measured in pure or naïve form, stocks with high DDM values tend to behave procyclically.

High B/P appears to be a better indicator of a defensive stock. It has a regression coefficient of −0.10 in naïve form. In pure form, however, B/P is virtually uncorrelated with market movements; pure B/P signals neither an aggressive nor a defensive stock. B/P as naïvely measured apparently picks up the effects of truly defensive variables, such as high yield.

The value investor in search of a defensive posture in uncertain market climates should consider moving toward high yield. The regression coefficients for both naïve and pure returns to high yield indicate significant negative market sensitivities. Stocks with high yields may be expected to lag in up markets but to hold up relatively well during general market declines.

These results make broad intuitive sense. DDM is forward-looking, relying on estimates of future earnings. In bull markets, investors take a long-term outlook, so DDM explains security pricing behavior. In bear markets, however, investors become myopic; they prefer today's tangible income to tomorrow's promise. Current yield is rewarded.

Pure returns respond in intuitively satisfying ways to macroeconomic events. Figure 5 illustrates, as an example, the estimated effects of changes in various macroeconomic variables on the pure returns to small size (as measured by

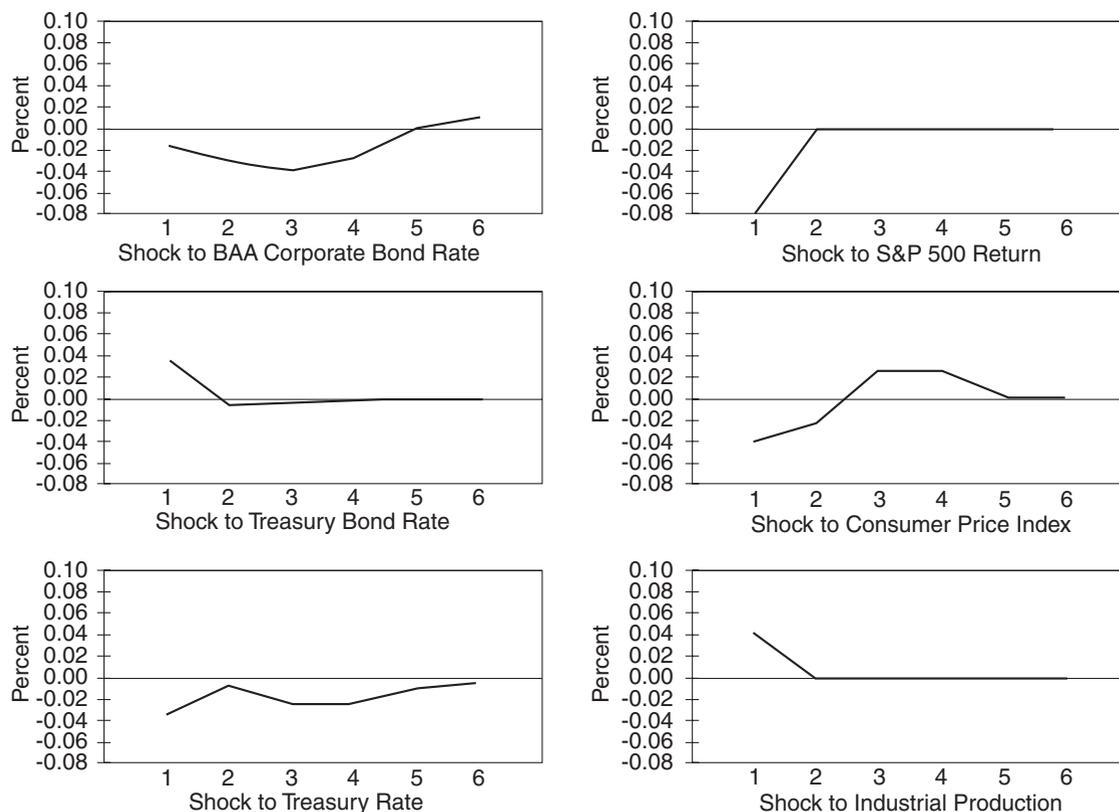

Figure 5 Forecast Response of Small Size to Macroeconomic Shocks

market capitalization). Consistent with the capital constraints on small firms and their relatively greater sensitivity to the economy, pure returns to small size may be expected to be negative in the first four months following an unexpected increase in the Baa corporate rate and positive in the first month following an unexpected increase in industrial production.⁸ Investors can exploit such predictable behavior by moving into and out of the small-cap market segment as economic conditions evolve.⁹

These examples serve to illustrate that the use of numerous, finely defined fundamental variables can provide a rich representation of the complexity of security pricing. The model can be even more finely tuned, however, by including variables that capture such subtleties as the effects of investor psychology, possible non-

linearities in variable-return relationships, and security transaction costs.

Additional Complexities

In considering possible variables for inclusion in a model of stock price behavior, the investor should recognize that pure stock returns are driven by a combination of economic fundamentals and investor psychology. That is, economic fundamentals such as interest rates, industrial production, and inflation can explain much, but by no means all, of the systematic variation in returns. Psychology, including investors' tendency to overreact, their desire to seek safety in numbers, and their selective memories, also plays a role in security pricing.

What's more, the modeler should realize that the effects of different variables, fundamental

and otherwise, can differ across different types of stocks. The value sector, for example, includes more financial stocks than the growth sector. Investors may thus expect value stocks in general to be more sensitive than growth stocks to changes in interest rate spreads.

Psychologically based variables such as short-term overreaction and price correction also seem to have a stronger effect on value than on growth stocks. Earnings surprises and earnings estimate revisions, by contrast, appear to be more important for growth than for value stocks. Thus, Google shares can take a nosedive when earnings come in a penny under expectations, whereas Duke Energy shares remain unmoved even by fairly substantial departures of actual earnings from expectations.

The relationship between stock returns and relevant variables may not be linear. The effects of positive earnings surprises, for instance, tend to be arbitrated away quickly; thus positive earnings surprises offer less opportunity for the investor. The effects of negative earnings surprises, however, appear to be more long-lasting. This nonlinearity may reflect the fact that sales of stock are limited to those investors who already own the stock (and to a relatively small number of short-sellers).¹⁰

Risk-variable relationships may also differ across different types of stock. In particular, small-cap stocks generally have more idiosyncratic risk than large-cap stocks. Diversification is thus more important for small-stock than for large-stock portfolios.

Return-variable relationships can also change over time. Recall the difference between DDM and yield value measures: high-DDM stocks tend to have high returns in bull markets and low returns in bear markets; high-yield stocks experience the reverse. For consistency of performance, return modeling must consider the effects of market dynamics, the changing nature of the overall market.

The investor may also want to decipher the informational signals generated by informed agents. Corporate decisions to issue or buy back

shares, split stock, or initiate or suspend dividends, for example, may contain valuable information about company prospects. So, too, may insiders' (legal) trading in their own firms' shares.

Finally, a complex model containing multiple variables is likely to turn up a number of promising return-variable relationships. But are these perceived profit opportunities translatable into real economic opportunities? Are some too ephemeral? Too small to survive frictions such as trading costs? Estimates of expected returns must be combined with estimates of the costs of trading to arrive at realistic returns net of trading costs.

CONSTRUCTING, TRADING, AND EVALUATING PORTFOLIOS

To maximize implementation of the model's insights, the portfolio construction process should consider exactly the same dimensions found relevant by the stock selection model. Failure to do so can lead to mismatches between model insights and portfolio exposures.¹¹

Consider a commercially available *portfolio optimizer* that recognizes only a subset of the variables in the valuation model. Risk reduction using such an optimizer will reduce the portfolio's exposures only along the dimensions the optimizer recognizes. As a result, the portfolio is likely to wind up more exposed to those variables recognized by the model, but not the optimizer, and less exposed to those variables common to both the model and the optimizer.

Imagine an investor who seeks low-P/E stocks that analysts are recommending for purchase, but who uses a commercial optimizer that incorporates a P/E factor but not analyst recommendations. The investor is likely to wind up with a portfolio that has a less-than-optimal level of exposure to low P/E and a greater-than-optimal level of exposure to

analyst purchase recommendations. Optimization using all relevant variables ensures a portfolio whose risk and return opportunities are balanced in accordance with the model's insights. Furthermore, the use of more numerous variables allows portfolio risk to be more finely tuned.

Insofar as the investment process, both stock selection and portfolio construction, is model-driven, it is more adaptable to electronic trading venues. This should benefit the investor in several ways. First, electronic trading is generally less costly, with lower commissions, market impact, and opportunity costs. Second, it allows real-time monitoring, which can further reduce trading costs. Third, an automated trading system can take account of more factors, including the urgency of a particular trade and market conditions, than individual traders can be expected to bear in mind.

Finally, the *performance attribution* process should be congruent with the dimensions of the selection model (and portfolio optimizer). Insofar as performance attribution identifies sources of return, a process that considers all the sources identified by the selection model will be more insightful than a commercial performance attribution system applied in a one-size-fits-all manner. Our investor who has sought exposure to low P/E and positive analyst recommendations, for example, will want to know how each of these factors has paid off and will be less interested in the returns to factors that are not a part of the stock selection process.

A performance evaluation process tailored to the model also functions as a monitor of the model's reliability. Has portfolio performance supported the model's insights? Should some be reexamined? Equally important, does the model's reliability hold up over time? A model that performs well in today's economic and market environments may not necessarily perform well in the future. A feedback loop between the evaluation and the research/modeling processes can help ensure that the model retains robustness over time.

PROFITING FROM COMPLEXITY

H. L. Mencken is supposed to have noted, "For every complex problem, there is a simple solution, and it is almost always wrong." Complex problems more often than not require complex solutions.

A complex approach to stock selection, portfolio construction, and performance evaluation is needed to capture the complexities of the stock market. Such an approach combines the breadth of coverage and the depth of analysis needed to maximize investment opportunity and potential reward.

Grinold presents a formula that identifies the relationships between the depth and breadth of investment insights and investment performance:¹²

$$IR = IC\sqrt{BR}$$

IR is the manager's information ratio, a measure of the success of the investment process. IR equals annualized excess return over annualized residual risk (e.g., 2% excess return with 4% tracking error provides 0.5 IR). IC, the information coefficient, or correlation between predicted and actual security returns, measures the goodness of the manager's insights, or the manager's skill. BR is the breadth of the strategy, measurable as the number of independent insights upon which investment decisions are made.

One can increase IR by increasing IC or BR. Increasing IC means coming up with some means of improving predictive accuracy. Increasing BR means coming up with more "investable" insights. A casino analogy may be apt (if anathema to prudent investors).

A gambler can seek to increase IC by card counting in blackjack or by building a computer model to predict probable roulette outcomes. Similarly, some investors seek to outperform by concentrating their research efforts on a few stocks: by learning all there is to know about Microsoft, for example, one may be able to

outperform all the other investors who follow this stock. But a strategy that makes a few concentrated stock bets is likely to produce consistent performance only if it is based on a very high level of skill, or if it benefits from extraordinary luck.

Alternatively, an investor can place a larger number of smaller stock bets and settle for more modest returns from a greater number of investment decisions. That is, rather than behaving like a gambler in a casino, the investor can behave like the casino. A casino has only a slight edge on any spin of the roulette wheel or roll of the dice, but many spins of many roulette wheels can result in a very consistent profit for the house. Over time, the odds will strongly favor the casino over the gambler.

A complex approach to the equity market, one that has both breadth of inquiry and depth of focus, can enhance the number and the goodness of investment insights. A complex approach to the equity market requires more time, effort, and ability, but it will be better positioned to capture the complexities of security pricing. The rewards are worth the effort.

KEY POINTS

- Ordered systems are definable and predictable by relatively simple rules; random systems cannot be modeled and are inherently unpredictable; complex systems can be at least partly comprehended and modeled, but only with difficulty.
- Stock price behavior is permeated by a complex web of interrelated return effects, and it requires a complex approach to stock selection, portfolio construction, and performance evaluation to capture this complexity.
- A complex approach combines the breadth of coverage and the depth of analysis needed to maximize investment opportunity and potential reward.
- Simple methods of measuring return effects (such as quintiling or univariate, single-variable regression) are naïve because they

assume that prices are responding only to the single variable under consideration.

- Simultaneous analysis of all relevant variables via multivariate regression takes into account and adjusts for interrelationships between effects, giving the return to each variable separately.
- Disentangling distinguishes real effects from mere proxies and thereby distinguishes between real and spurious investment opportunities.
- Because disentangling controls for proxy effects, pure return effects are additive, each having the potential to improve portfolio performance.
- In general, disentangling enhances the predictive power of estimated returns by providing a clearer picture of the relationships between investor behavior, fundamental variables, and macroeconomic conditions.
- To maximize implementation of insights gained from disentangling the market's complexity, the portfolio construction process should consider exactly the same dimensions found relevant by the stock selection process.
- Performance attribution should be congruent with the stock selection and portfolio construction processes so that it can be used to monitor the reliability of the stock selection process and provide input for research.

Equity Portfolio Selection Models in Practice

DESSISLAVA A. PACHAMANOVA, PhD

Associate Professor of Operations Research, Babson College

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Quantitative equity portfolio selection often involves extending the classical mean-variance framework or more advanced tail-risk portfolio allocation frameworks to include different constraints that take specific investment guidelines and institutional features into account. Examples of such constraints are holding constraints that set limits on the total concentration of assets in an industry, sector, or country; turnover constraints that restrict the amount of trading; tracking error constraints that limit the difference between the performance of the portfolio and a benchmark; and risk factor constraints that limit the exposure of the portfolio to a risk factor such as the market. Portfolio allocation models can also account for transaction costs, taxes, and optimization of trades across multiple client accounts. An important practical issue in quantitative equity portfolio selection is how to mitigate the effect of model and estimation errors on the optimal allocation. Techniques that are used to address this issue include robust statistical techniques for parameter estimation, portfolio resampling, and robust optimization.

An integrated investment process generally involves the following activities:¹

1. An investor's objectives, preferences, and constraints are identified and specified to develop explicit investment policies.
2. Strategies are developed and implemented through the choice of optimal combinations of financial and real assets in the marketplace.
3. Market conditions, relative asset values, and the investor's circumstances are monitored.

4. Portfolio adjustments are made as appropriate to reflect significant changes in any or all of the relevant variables.

In this entry we focus on the second activity of the investment process, developing and implementing a portfolio strategy. The development of the portfolio strategy itself is typically done in two stages: First, funds are allocated among asset classes. Then, they are managed within the asset classes. The mean-variance framework is used at both stages,

but in this entry, we discuss the second stage. Specifically, we introduce quantitative formulations of portfolio allocation problems used in equity portfolio management. Quantitative equity portfolio selection often involves extending the classical mean-variance framework or more advanced tail-risk portfolio allocation frameworks to include different constraints that take specific investment guidelines and institutional features into account.

We begin by providing a classification of the most common *portfolio constraints* used in practice. We then discuss extensions such as index tracking formulations, the inclusion of transaction costs, optimization of trades across multiple client accounts, and tax-aware strategies. We conclude with a review of methods for incorporating robustness in quantitative portfolio allocation procedures by using robust statistics, simulation, and robust optimization techniques.

PORTFOLIO CONSTRAINTS COMMONLY USED IN PRACTICE

Institutional features and investment policy specifications often lead to more complicated requirements than simple minimization of risk (whatever the definition of risk may be) or maximization of expected portfolio return. For instance, there can be constraints that limit the number of trades, the exposure to a specific industry, or the number of stocks to be kept in the portfolio. Some of these constraints are imposed by the clients, while others are imposed by regulators. For example, in the case of regulated investment companies, restrictions on asset allocation are set forth in the prospectus and may be changed only with the approval of the fund's board of directors. Pension funds must comply with Employee Retirement Income Security Act (ERISA) requirements. The objective of the *portfolio optimization* problem can also be

modified to consider specifically the trade-off between risk and return, transactions costs, or taxes.

In this section, we will take a single-period view of investing, in the sense that the goal of the portfolio allocation procedure will be to invest optimally over a single predetermined period of interest, such as one month.² We will use \mathbf{w}_0 to denote the vector array of stock weights in the portfolio at the beginning of the period, and \mathbf{w} to denote the weights at the end of the period (to be determined).

Many investment companies, especially institutional investors, have a long investment horizon. However, in reality, they treat that horizon as a sequence of shorter period horizons. Risk budgets are often stated over a time period of a year, and return performance is monitored quarterly or monthly.

Long-Only (No-Short-Selling) Constraints

Many funds and institutional investors face restrictions or outright prohibitions on the amount of short selling they can do. When short selling is not allowed, the portfolio allocation optimization model contains the constraints $\mathbf{w} \geq \mathbf{0}$.

Holding Constraints

Diversification principles argue against investing a large proportion of the portfolio in a single asset, or having a large concentration of assets in a specific industry, sector, or country. Limits on the holdings of a specific stock can be imposed with the constraints

$$\mathbf{l} \leq \mathbf{w} \leq \mathbf{u}$$

where \mathbf{l} and \mathbf{u} are vectors of lower and upper bounds of the holdings of each stock in the portfolio.

Consider now a portfolio of 10 stocks. Suppose that the issuers of assets 1, 3, and 5 are in

the same industry, and that we would like to limit the portfolio exposure to that industry to be at least 20% but at most 40%. To limit exposure to that industry, we add the constraint

$$0.20 \leq w_1 + w_3 + w_5 \leq 0.40$$

to the portfolio allocation optimization problem.

More generally, if we have a specific set of stocks I_j out of the investment universe I consisting of stocks in the same category (such as industry or country), we can write the constraint

$$L_j \leq \sum_{j \in I_j} w_j \leq U_j$$

In words, this constraint requires that the sum of all stock weights in the particular category of investments with indexes I_j is greater than or equal to a lower bound L_j and less than or equal to a maximum exposure of U_j .

Turnover Constraints

High portfolio turnover can result in large transaction costs that make portfolio rebalancing inefficient and costly. Thus, some portfolio managers limit the amount of turnover allowed when trading their portfolio. (Another way to control for transaction costs is to minimize them explicitly; we will discuss the appropriate formulations later in this entry.)

Most commonly, turnover constraints are imposed for each stock:

$$|w_i - w_{0,i}| \leq u_i,$$

that is, the absolute magnitude of the difference between the final and the initial weight of stock i in the portfolio is restricted to be less than some upper bound u_i . Sometimes, a constraint is imposed to minimize the portfolio turnover as a whole:

$$\sum_{j \in I_j} |w_j - w_{0,j}| \leq U_j$$

that is, the total absolute difference between the initial and the final weights of the stocks in the portfolio is restricted to be less than or equal to an upper bound U_j . Under this constraint, some stock weights may deviate a lot more than others from their initial weights, but the total deviation is limited.

Turnover constraints are often imposed relative to the *average daily volume* (ADV) of a stock.³ For example, we may want to restrict turnover to be no more than 5% of the ADV. (In the latter case, the upper bound u_i is set to a value equal to 5% of the ADV.) Modifications of these constraints, such as limiting turnover in a specific industry or sector, are also frequently applied.

Risk Factor Constraints

In practice, it is very common for quantitatively oriented portfolio managers to use factor models to control for risk exposures to different risk factors. Such risk factors could include the market return, size, and style. Let us assume that the return on stock i has a factor structure with K risk factors, that is, it can be expressed through the equality

$$r_i = \alpha_i + \sum_{k=1}^K \beta_{ik} \cdot f_k + \varepsilon_i$$

The factors f_k are common to all securities. The coefficient β_{ik} in front of each factor f_k shows the sensitivity of the return on stock i to factor k . The value of α_i shows the expected excess return of the return on stock i , and ε_i is the idiosyncratic (called “nonsystematic”) part of the return of stock i . The coefficients α_i and β_{ik} are typically estimated by multiple regression analysis.

To limit the exposure of a portfolio of N stocks to the k th risk factor, we impose the constraint

$$\sum_{i=1}^N \beta_{ik} \cdot w_i \leq U_k$$

To understand this constraint, note that the total return on the portfolio can be written as

$$\begin{aligned} \sum_{i=1}^N w_i \cdot r_i &= \sum_{i=1}^N w_i \cdot (\alpha_i + \sum_{k=1}^K \beta_{ik} \cdot f_k + \varepsilon_i) \\ &= \sum_{i=1}^N w_i \cdot \alpha_i + \sum_{i=1}^N \left(w_i \cdot \left(\sum_{k=1}^K \beta_{ik} \cdot f_k \right) \right) \\ &\quad + \sum_{i=1}^N w_i \cdot \varepsilon_i \end{aligned}$$

The sensitivity of the portfolio to the different factors is represented by the second term, which can be also written as

$$\sum_{k=1}^K \left(\left(\sum_{i=1}^N w_i \cdot \beta_{ik} \right) \cdot f_k \right)$$

Therefore, the exposure to a particular factor k is the coefficient in front of f_k , that is,

$$\sum_{i=1}^N \beta_{ik} \cdot w_i$$

On an intuitive level, the sensitivity of the portfolio to a factor k will be larger the larger the presence of factor k in the portfolio through the exposure of the individual stocks. Thus, when we compute the total exposure of the portfolio to factor k , we need to take into consideration both how important this factor is for determining the return on each of the securities in the portfolio, and how much of each security we have in the portfolio.

A commonly used version of the maximum factor exposure constraint is

$$\sum_{i=1}^N \beta_{ik} \cdot w_i = 0$$

This constraint forces the portfolio optimization algorithm to find portfolio weights so that the overall risk exposure to factor k is 0, that is, so that the portfolio is neutral with respect to changes in factor k . Portfolio allocation strategies that claim to be “market-neutral” typically employ this constraint, and the factor is in fact the return on the market.

Cardinality Constraints

Depending on the portfolio allocation model used, sometimes the optimization subroutine recommends holding small amounts of a large number of stocks, which can be costly when one takes into consideration the transaction costs incurred when acquiring these positions. Alternatively, a portfolio manager may be interested in limiting the number of stocks used to track a particular index. (We will discuss index tracking later in this entry.) To formulate the constraint on the number of stocks to be held in the portfolio (called the cardinality constraint), we introduce binary variables, one for each of the N stocks in the portfolio. Let us call these binary variables $\delta_1, \dots, \delta_N$. Variable δ_i will take value 1 if stock i is included in the portfolio, and 0 otherwise.

Suppose that out of the N stocks in the investment universe, we would like to include a maximum of K stocks in the final portfolio. K here is a positive integer and is less than N . This constraint can be formulated as

$$\sum_{i=1}^N \delta_i \leq K$$

$$\delta_i \text{ binary, } i = 1, \dots, N$$

We need to make sure, however, that if a stock is not selected in the portfolio, then the binary variable that corresponds to that stock is set to 0, so that the stock is not counted as one of the K stocks left in the portfolio. When the portfolio weights are restricted to be nonnegative, this can be achieved by imposing the additional constraints

$$0 \leq w_i \leq \delta_i, \quad i = 1, \dots, N$$

If the optimal weight for stock i turns out to be different from 0, then the binary variable δ_i associated with stock i is forced to take value 1, and stock i will be counted as one of the K stocks to be kept in the portfolio. If the optimal weight for stock i is 0, then the binary variable δ_i associated with stock i can be either 0 or 1, but that will not matter for all practical

purposes, because the solver will set it to 0 if there are too many other attractive stocks that will be counted as the K stocks to be kept in the portfolio. At the same time, since the portfolio weights w_i are between 0 and 1, and δ_i is 0 or 1, the constraint $w_i \leq \delta_i$ does not restrict the values that the stock weight w_i can take.

The constraints are a little different if short sales are allowed, in which case the weights may be negative. We have

$$-M \cdot \delta_i \leq w_i \leq M \cdot \delta_i, \quad i = 1, \dots, N$$

where M is a “large” constant (large relative to the size of the inputs in the problem; so in this portfolio optimization application $M = 10$ can be considered “large”). You can observe that if the weight w_i is anything but 0, the value of the binary variable δ_i will be forced to be different from 0, that is, δ_i will need to be 1, since it can only take values 0 or 1.

Minimum Holding and Transaction Size Constraints

Cardinality constraints are often used in conjunction with minimum holding/trading constraints. The latter set a minimum limit on the amount of a stock that can be held in the portfolio, or the amount of a stock that can be traded, effectively eliminating small trades. Both cardinality and minimum holding/trading constraints aim to reduce the amount of transaction costs.

Threshold constraints on the amount of stock i to be held in the portfolio can be imposed with the constraint

$$|w_i| \geq L_i \cdot \delta_i$$

where L_i is the smallest holding size allowed for stock i , and δ_i is a binary variable, analogous to the binary variables δ_i defined in the previous section—it equals 1 if stock i is included in the portfolio, and 0 otherwise. (All additional constraints relating δ_i and w_i described in the previous section still apply.)

Similarly, constraints can be imposed on the minimum trading amount for stock i . As we ex-

plained earlier in this section, the size of the trade for stock i is determined by the absolute value of the difference between the current weight of the stock, $w_{0,i}$, and the new weight w_i that will be found by the solver: $|w_i - w_{0,i}|$. The minimum trading size constraint formulation is

$$|w_i - w_{0,i}| \geq L_i^{\text{trade}} \cdot \delta_i$$

where L_i^{trade} is the smallest trading size allowed for stock i .

Adding binary variables to an optimization problem makes the problem more difficult for the solver and can increase the computation time substantially. That is why in practice, portfolio managers often omit minimum holding and transaction size constraints from the optimization problem formulation, selecting instead to eliminate weights and/or trades that appear too small manually, after the optimal portfolio is determined by the optimization solver. It is important to realize, however, that modifying the optimal solution for the simpler portfolio allocation problem (the optimal solution in this case is the weights/trades for the different stocks) by eliminating small positions manually does not necessarily produce the optimal solution to an optimization problem that contained the minimum holding and transaction size constraints from the beginning. In fact, there can be pathological cases in which the solution is very different from the true optimal solution. However, for most cases in practice, the small manual adjustments to the optimal portfolio allocation do not cause tremendous discrepancies or inconsistencies.

Round Lot Constraints

So far, we have assumed that stocks are infinitely divisible, that is, that we can trade and invest in fractions of stocks, bonds, and so on. This is, of course, not true—in reality, securities are traded in multiples of minimum transaction lots, or rounds (e.g., 100 or 500 shares).

In order to represent the condition that securities should be traded in rounds, we need to introduce additional decision variables (let us

call them z_i , $i = 1, \dots, N$) that are integers and will correspond to the number of lots of a particular security that will be purchased. Each z_i will then be linked to the corresponding portfolio weight w_i through the equality

$$w_i = z_i \cdot f_i, \quad i = 1, \dots, N$$

where f_i is measured in dollars, and is a fraction of the total amount to be invested. For example, suppose there is a total of \$100 million to be invested, and stock i trades at \$50 in round lots of 100. Then

$$f_i = \frac{50 \cdot 100}{100,000,000} = 5 \cdot 10^{-7}$$

All remaining constraints in the portfolio allocation can be expressed through the weights w_i , as usual. However, we also need to specify for the solver that the decision variables z_i are integers.

An issue with imposing round lot constraints is that the budget constraint

$$\mathbf{w}'\mathbf{t} = 1$$

which is in fact

$$\sum_{i=1}^N z_i \cdot f_i = 1$$

may not be satisfied exactly. One possibility to handle this problem is to relax the budget constraint. For example, we can state the constraint as

$$\mathbf{w}'\mathbf{t} \leq 1$$

or, equivalently,

$$\sum_{i=1}^N z_i \cdot f_i \leq 1$$

This will ensure that we do not go over budget.

If our objective is stated as expected return maximization, the optimization solver will attempt to make this constraint as tight as possible, that is, we will end up using up as much of the budget as we can. Depending on the objective function and the other constraints in the formulation, however, this may not always happen. We can try to force the solver to minimize

the slack in the budget constraint by introducing a pair of nonnegative decision variables (let us call them ε^+ and ε^-) that account for the amount that is “overinvested” or “underinvested.” These variables will pick up the slack left over because of the inability to round the amounts for the different investments. Namely, we impose the constraints

$$\begin{aligned} \sum_{i=1}^N z_i \cdot f_i + \varepsilon^- - \varepsilon^+ &= 1 \\ \varepsilon^- \geq 0, \varepsilon^+ &\geq 0 \end{aligned}$$

and subtract the following term from the objective function:

$$\lambda_{\text{rl}} \cdot (\varepsilon^- + \varepsilon^+)$$

where λ_{rl} is a penalty term associated with the amount of over- or underinvestment the portfolio manager is willing to tolerate (selected by the portfolio manager). In the final solution, the violation of the budget constraint will be minimized. Note, however, that this formulation technically allows for the budget to be overinvested.

The optimal portfolio allocation we obtain after solving this optimization problem will not be the same as the allocation we would obtain if we solve an optimization problem without round lot constraints, and then round the amounts to fit the lots that can be traded in the market.

Cardinality constraints, minimum holding/trading constraints, and especially round lot constraints require more sophisticated binary and integer programming solvers, and are difficult problems to solve in the case of large portfolios.

BENCHMARK EXPOSURE AND TRACKING ERROR MINIMIZATION

Expected portfolio return maximization under the mean-variance framework or other risk measure minimization are examples of *active*

investment strategies, that is, strategies that identify a universe of attractive investments and ignore inferior investments opportunities. A different approach, referred to as a *passive investment strategy*, argues that in the absence of any superior forecasting ability, investors might as well resign themselves to the fact that they cannot beat the market. From a theoretical perspective, the analytics of portfolio theory tell them to hold a broadly diversified portfolio anyway. Many mutual funds are managed relative to a particular benchmark or stock universe, such as the S&P 500 or the Russell 1000. The portfolio allocation models are then formulated in such a way that the tracking error relative to the benchmark is kept small.

Standard Definition of Tracking Error

To incorporate a passive investment strategy, we can change the objective function of the portfolio allocation problem so that instead of minimizing a portfolio risk measure, we minimize the tracking error with respect to a benchmark that represents the market, such as the Russell 3000, or the S&P 500. Such strategies are often referred to as *indexing*. The *tracking error* can be defined in different ways. However, practitioners typically mean a specific definition: the variance (or standard deviation) of the difference between the portfolio return, $\mathbf{w}'\tilde{\mathbf{r}}$, and the return on the benchmark, $\mathbf{w}_b'\tilde{\mathbf{r}}$. Mathematically, the tracking error (TE) can be expressed as

$$\begin{aligned} \text{TE} &= \text{Var}(\mathbf{w}'\tilde{\mathbf{r}} - \mathbf{w}_b'\tilde{\mathbf{r}}) \\ &= \text{Var}((\mathbf{w} - \mathbf{w}_b)'\tilde{\mathbf{r}}) \\ &= (\mathbf{w} - \mathbf{w}_b)'\text{Var}(\tilde{\mathbf{r}})(\mathbf{w} - \mathbf{w}_b) \\ &= (\mathbf{w} - \mathbf{w}_b)'\boldsymbol{\Sigma}(\mathbf{w} - \mathbf{w}_b) \end{aligned}$$

where $\boldsymbol{\Sigma}$ is the covariance matrix of the stock returns. One can observe that the formula is very similar to the formula for the portfolio variance; however, the portfolio weights in the formula for the variance are replaced by differences between the weights of the stocks in the portfolio and the weights of the stocks in the index.

Why do we need to optimize portfolio weights in order to track a benchmark, when technically the most effective way to track a benchmark is by investing the portfolio in the stocks in the benchmark portfolio in the same proportions as the proportions of these securities in the benchmark? The problem with this approach is that, especially with large benchmarks like the Russell 3000, the transaction costs of a proportional investment and the subsequent rebalancing of the portfolio can be prohibitive (that is, dramatically adversely impact the performance of the portfolio relative to the benchmark). Furthermore, in practice securities are not infinitely divisible, so investing a portfolio of a limited size in the same proportions as the composition of the benchmark will still not achieve zero tracking error. Thus, the optimal formulation is to require that the portfolio follows the benchmark as closely as possible.

While indexing has become an essential part of many portfolio strategies, most portfolio managers cannot resist the temptation to identify at least some securities that will outperform others. Hence, restrictions on the tracking error are often imposed as a constraint, while the objective function is something different from minimizing the tracking error. The tracking error constraint takes the form

$$(\mathbf{w} - \mathbf{w}_b)'\boldsymbol{\Sigma}(\mathbf{w} - \mathbf{w}_b) \leq \sigma_{\text{TE}}^2$$

where σ_{TE}^2 is a limit (imposed by the investor) on the amount of tracking error the investor is willing to tolerate. This is a quadratic constraint, which is convex and computationally tractable, but requires specialized optimization software.

Alternative Ways of Defining Tracking Error

There are alternative ways in which tracking-error type constraints can be imposed.

For example, we may require that the absolute deviations of the portfolio weights (\mathbf{w}) from the index weights (\mathbf{w}_b) are less than or equal to a

given vector array of upper bounds \mathbf{u} :

$$|\mathbf{w} - \mathbf{w}_b| \leq \mathbf{u}$$

where the absolute values $|\cdot|$ for the vector differences are taken componentwise, that is, for pairs of corresponding elements from the two vector arrays. These constraints can be stated as linear constraints by rewriting them as

$$\begin{aligned} \mathbf{w} - \mathbf{w}_b &\leq \mathbf{u} \\ -(\mathbf{w} - \mathbf{w}_b) &\leq \mathbf{u} \end{aligned}$$

Similarly, we can require that for stocks within a specific industry (whose indexes in the portfolio belong to a subset I_j of the investment universe I), the total tracking error is less than a given upper bound U_j :

$$\sum_{j \in I_j} (w_j - w_{b,j}) \leq U_j$$

Finally, tracking error can be expressed through risk measures other than the absolute deviations or the variance of the deviations from the benchmark. Rockafellar and Uryasev (2000) suggest using conditional value-at-risk (CVaR) to manage the tracking error. Conditional value-at-risk measures the average loss that can happen with probability less than some small probability, that is, the average loss in the tail of the distribution of portfolio losses. (Using CVaR as a risk measure results in computationally tractable optimization formulations for portfolio allocation, as long as the data are presented in the form of scenarios.⁴) We provide below a formulation that is somewhat different from Rockafellar and Uryasev, but preserves the main idea.

Suppose that we are given S scenarios for the return of a benchmark portfolio (or an instrument we are trying to replicate), $b_s, s = 1, \dots, S$. These scenarios can be generated by simulation or taken from historical data. We also have N stocks with returns $r_i^{(s)} (i = 1, \dots, N, s = 1, \dots, S)$ in each scenario. The value of the portfolio in scenario s is

$$\sum_{i=1}^N r_i^{(s)} \cdot w_i$$

or, equivalently, $(\mathbf{r}^{(s)})' \mathbf{w}$, where $\mathbf{r}^{(s)}$ is the vector of returns for the N stocks in scenario s . Consider the differences between the return on the benchmark and the return on the portfolio,

$$b_s - (\mathbf{r}^{(s)})' \mathbf{w} = -((\mathbf{r}^{(s)})' \mathbf{w} - b_s)$$

If this difference is positive, we have a loss; if the difference is negative, we have a gain; both gains and losses are computed relative to the benchmark. Rationally, the portfolio manager should not worry about differences that are negative; the only cause for concern would be if the portfolio underperforms the benchmark, which would result in a positive difference. Thus, it is not necessary to limit the variance of the deviations of the portfolio returns from the benchmark, which penalizes for positive and negative deviations equally. Instead, we can impose a limit on the amount of loss we are willing to tolerate in terms of the CVaR of the distribution of losses relative to the benchmark.

The tracking error constraint in terms of the CVaR can be stated as the following set of constraints:⁵

$$\begin{aligned} \xi + \frac{1}{[\varepsilon \cdot S]} \cdot \sum_{s=1}^S y_s &\leq U_{TE} \\ y_s &\geq -\left((\mathbf{r}^{(s)})' \mathbf{w} - b_s\right) - \xi, \quad s = 1, \dots, S \\ y_s &\geq 0, \quad s = 1, \dots, S \end{aligned}$$

where U_{TE} is the upper bound on the negative deviations.

This formulation of tracking error is appealing in two ways. First, it treats positive and negative deviations relative to the benchmark differently, which agrees with the strategy of an investor seeking to maximize returns overall. Second, it results in a linear set of constraints, which are easy to handle computationally, in contrast to the first formulation of the tracking error constraint in this section, which results in a quadratic constraint.

Actual Versus Predicted Tracking Error

The tracking error calculation in practice is often backward-looking. For example, in computing the covariance matrix Σ in the standard tracking error definition as the variance of the deviations of the portfolio returns from the index, or in selecting the scenarios used in the CVaR-type tracking error constraint in the previous section, we may use historical data. The tracking error calculated in this manner is called the *ex post* tracking error, backward-looking error, or actual tracking error.

The problem with using the actual tracking error for assessing future performance relative to a benchmark is that the actual tracking error does not reflect the effect of the portfolio manager's current decisions on the future active returns and hence the tracking error that may be realized in the future. The actual tracking error has little predictive value and can be misleading regarding portfolio risk.

Portfolio managers need forward-looking estimates of tracking error to reflect future portfolio performance more accurately. In practice, this is accomplished by using the services of a commercial vendor that has a multifactor risk model that has identified and defined the risks associated with the benchmark, or by building such a model in-house. Statistical analysis of historical return data for the stocks in the benchmark is used to obtain the risk factors and to quantify the risks. Using the manager's current portfolio holdings, the portfolio's current exposure to the various risk factors can be calculated and compared to the benchmark's exposures to the risk factors. From the differential factor exposures and the risks of the factors, a forward-looking tracking error for the portfolio can be computed. This tracking error is also referred to as an *ex ante* tracking error or predicted tracking error.

There is no guarantee that the predicted tracking error will match exactly the tracking error realized over the future time period of interest. However, this calculation of the tracking error

has its use in risk control and portfolio construction. By performing a simulation analysis on the factors that enter the calculation, the manager can evaluate the potential performance of portfolio strategies relative to the benchmark, and eliminate those that result in tracking errors beyond the client-imposed tolerance for risk. The actual tracking error, on the other hand, is useful for assessing actual performance relative to a benchmark.

INCORPORATING TRANSACTION COSTS

Transaction costs can be generally divided into two categories: (1) explicit such as bid-ask spreads, commissions, and fees, and (2) implicit such as price movement risk costs and market impact costs. Price movement risk costs are the costs resulting from the potential for a change in market price between the time the decision to trade is made and the time the trade is actually executed. Market impact is the effect a trader has on the market price of an asset when it sells or buys the asset. It is the extent to which the price moves up or down in response to the trader's actions. For example, a trader who tries to sell a large number of shares of a particular stock may drive down the stock's market price.

The typical portfolio allocation models are built on top of one or several forecasting models for expected returns and risk. Small changes in these forecasts can result in reallocations that would not occur if transaction costs are taken into account. In practice, the effect of transaction costs on portfolio performance is far from insignificant. If transaction costs are not taken into consideration in allocation and rebalancing decisions, they can lead to poor portfolio performance.

This section describes some common transaction cost models for portfolio rebalancing. We use the mean-variance framework as the basis for describing the different approaches. However, it is straightforward to extend the

transaction cost models into other portfolio allocation frameworks.

The earliest, and most widely used, model for transaction costs is the mean-variance risk-aversion formulation with transaction costs.⁶ The optimization problem has the following objective function:

$$\max_{\mathbf{w}} \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \lambda_{\text{TC}} \cdot \text{TC}$$

where TC is a transaction cost penalty function and λ_{TC} is the transaction cost aversion parameter. In other words, the objective is to maximize the expected portfolio return less the cost of risk and transaction costs. We can imagine that as the transaction costs increase, at some point it becomes optimal to keep the current portfolio rather than to rebalance. Variations of this formulation exist. For example, it is common to maximize expected portfolio return minus transaction costs, and to impose limits on the risk as a constraint (i.e., to move the second term in the objective function to the constraints).

Transaction costs models can involve complicated nonlinear functions. Although software exists for general nonlinear optimization problems, the computational time required for solving such problems is often too long for realistic investment applications, and the quality of the solution is not guaranteed. In practice, an observed complicated nonlinear transaction costs function is often approximated with a computationally tractable function that is assumed to be separable in the portfolio weights, that is, it is often assumed that the transaction costs for each individual stock are independent of the transaction costs for another stock. For the rest of this section, we will denote the individual cost function for stock i by TC_i .

Next, we explain several widely used models for the transaction cost function.

Linear Transaction Costs

Let us start simple. Suppose that the transaction costs are proportional, that is, they are a percentage c_i of the transaction size $|t| =$

$|w_i - w_{0,i}|$.⁷ Then, the portfolio allocation problem with transaction costs can be written simply as

$$\max_{\mathbf{w}} \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \lambda_{\text{TC}} \cdot \sum_{i=1}^N c_i \cdot |w_i - w_{0,i}|$$

The problem can be made solver-friendly by replacing the absolute value terms with new decision variables y_i , and adding two sets of constraints. Hence, we rewrite the objective function as

$$\max_{\mathbf{w}, \mathbf{y}} \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \lambda_{\text{TC}} \cdot \sum_{i=1}^N c_i \cdot y_i$$

and add the constraints

$$\begin{aligned} y_i &\geq w_i - w_{0,i} \\ y_i &\geq -(w_i - w_{0,i}) \end{aligned}$$

This preserves the quadratic optimization problem formulation, a formulation that can be passed to quadratic optimization solvers such as Excel Solver and MATLAB's `quadprog` function, because the constraints are linear expressions, and the objective function contains only linear and quadratic terms.

In the optimal solution, the optimization solver will in fact set the value for y_i to $|w_i - w_{0,i}|$. This is because this is a maximization problem and y_i occurs with a negative sign in the objective function, so the solver will try to set y_i to the minimum value possible. That minimum value will be the maximum of $(w_i - w_{0,i})$ or $-(w_i - w_{0,i})$, which is in fact the absolute value $|w_i - w_{0,i}|$.

Piecewise-Linear Transaction Costs

Taking the model in the previous section a step further, we can introduce piecewise-linear approximations to transaction cost function models. This kind of function is more realistic than the linear cost function, especially for large trades. As the trading size increases, it becomes increasingly more costly to trade because of the market impact of the trade.

An example of a piecewise-linear function of transaction costs for a trade of size t of a

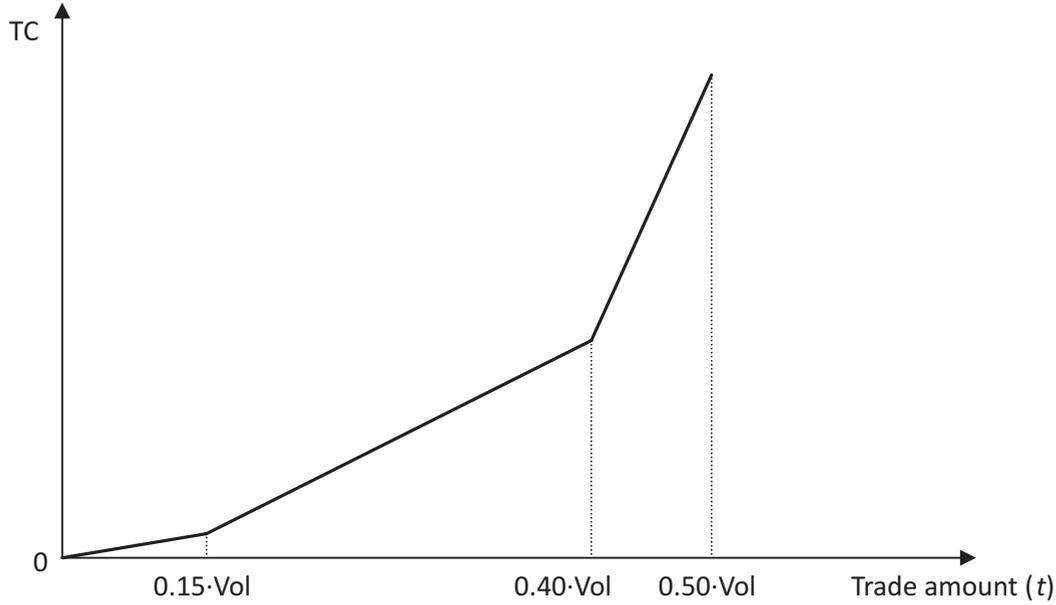

Figure 1 Example of Modeling Transaction Costs (TC) as a Piecewise-Linear Function of Trade Size t

particular security is illustrated in Figure 1. The transaction cost function in the graph assumes that the rate of increase of transaction costs (reflected in the slope of the function) changes at certain threshold points. For example, it is smaller in the range 0 to 15% of daily volume than in the range 15% to 40% of daily volume (or some other trading volume index). Mathematically, the transaction cost function in Figure 1 can be expressed as

$$TC(t) = \begin{cases} s_1 t, & 0 \leq t \leq 0.15 \cdot \text{Vol} \\ s_1(0.15 \cdot \text{Vol}) + s_2(t - 0.15 \cdot \text{Vol}), & 0.15 \cdot \text{Vol} \leq t \leq 0.40 \cdot \text{Vol} \\ s_1(0.15 \cdot \text{Vol}) + s_2(0.25 \cdot \text{Vol}) + s_3(t - 0.40 \cdot \text{Vol}), & 0.40 \cdot \text{Vol} \leq t \leq 0.50 \cdot \text{Vol} \end{cases}$$

where s_1, s_2, s_3 are the slopes of the three linear segments on the graph. (They are given data.)

To include piecewise-linear functions for transaction costs in the objective function of a mean-variance (or any general mean-risk) portfolio optimization problem, we need to introduce new decision variables that correspond to the number of pieces in the piecewise-linear approximation of the transaction cost function (in this case, there are three linear segments, so

we introduce variables z_1, z_2, z_3). We write the penalty term in the objective function for an individual stock as⁸

$$\lambda_{TC} \cdot (s_1 \cdot z_1 + s_2 \cdot z_2 + s_3 \cdot z_3)$$

If there are N stocks in the portfolio, the total transaction cost will be the sum of the transaction costs for each individual stock, that is, the penalty term that involves transaction costs in the objective function becomes

$$-\lambda_{TC} \sum_{i=1}^N (s_{1,i} \cdot z_{1,i} + s_{2,i} \cdot z_{2,i} + s_{3,i} \cdot z_{3,i})$$

In addition, we specify the following constraints on the new decision variables:

$$\begin{aligned} 0 &\leq z_{1,i} \leq 0.15 \cdot \text{Vol}_i \\ 0 &\leq z_{2,i} \leq 0.25 \cdot \text{Vol}_i \\ 0 &\leq z_{3,i} \leq 0.10 \cdot \text{Vol}_i \end{aligned}$$

Note that because of the increasing slopes of the linear segments and the goal of making that term as small as possible in the objective function, the optimizer will never set the decision variable corresponding to the second segment, $z_{2,i}$, to a number greater than 0 unless the decision variable corresponding to the first segment, $z_{1,i}$, is at its upper bound. Similarly,

the optimizer would never set $z_{3,i}$ to a number greater than 0 unless both $z_{1,i}$ and $z_{2,i}$ are at their upper bounds. So, this set of constraints allows us to compute the amount of transaction costs incurred in the trading of stock i as $z_{1,i} + z_{2,i} + z_{3,i}$.

Of course, we also need to link the amount of transaction costs incurred in the trading of stock i to the optimal portfolio allocation. This can be done by adding a few more variables and constraints. We introduce variables y_i , one for each stock in the portfolio, that would represent the amount traded (but not the direction of the trade) and would be nonnegative. Then, we require that

$$y_i = z_{1,i} + z_{2,i} + z_{3,i} \quad \text{for each stock } i,$$

and also that y_i equals the change in the portfolio position of stock i . The latter condition can be imposed by writing the constraint

$$y_i = |w_i - w_{0,i}|$$

where $w_{0,i}$ and w_i are the initial and the final amount of stock i in the portfolio, respectively.⁹

Despite their apparent complexity, piecewise-linear approximations for transaction costs are very solver-friendly, and save time (relative to nonlinear models) in the actual portfolio optimization. Although modeling transaction costs this way requires introducing new decision variables and constraints, the increase in the dimension of the portfolio optimization problem does not affect significantly the running time or the performance of the optimization solver, because the problem formulation is easy from a computational perspective.

Quadratic Transaction Costs

The transaction cost function is often parameterized as a quadratic function of the form

$$\text{TC}_i(t) = c_i \cdot |t| + d_i \cdot |t|^2$$

The coefficients c_i and d_i are calibrated from data—for example, by fitting a quadratic function to an observed pattern of transaction costs

realized for trading a particular stock under normal conditions.

Including this function in the objective function of the portfolio optimization problem results in a quadratic program that can be solved with widely available quadratic optimization software.

Fixed Transaction Costs

In some cases, we need to model fixed transaction costs. Those are costs that are incurred independently of the amount traded. To include such costs in the portfolio optimization problem, we need to introduce binary variables $\delta_1, \dots, \delta_N$ corresponding to each stock, where δ_i equals 0 if the amount traded of stock i is 0, and 1 otherwise. The idea is similar to the idea we used to model the requirement that only a given number of stocks can be included in the portfolio.

Suppose the fixed transaction cost is a_i for stock i . Then, the transaction cost function is

$$\text{TC}_i = a_i \cdot \delta_i$$

The objective function formulation is then

$$\max_{\mathbf{w}, \delta} \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \lambda_{\text{TC}} \cdot \sum_{i=1}^N a_i \cdot \delta_i$$

and we need to add the following constraints to make sure that the binary variables are linked to the trades $|w_i - w_{0,i}|$:

$$|w_i - w_{0,i}| \leq M \cdot \delta_i, \quad i = 1, \dots, N,$$

δ_i binary

where M is a “large” constant. When the trading size $|w_i - w_{0,i}|$ is nonzero, δ_i will be forced to be 1. When the trading size is 0, then δ_i can be either 0 or 1, but the optimizer will set it to 0, since it will try to make its value the minimum possible in the objective function.

Of course, combinations of different trading cost models can be used in practice. For example, if the trade involves both a fixed and a variable quadratic transaction cost, then we could

use a transaction cost function of the kind

$$TC_i(t) = a_i \cdot \delta_i + c_i \cdot |t| + d_i \cdot |t|^2$$

The important takeaway from this section is that when transaction costs are included in the portfolio rebalancing problem, the result is a reduced amount of trading and rebalancing, and a different portfolio allocation than the one that would be obtained if transaction costs are not taken into consideration.

INCORPORATING TAXES

When stocks in a portfolio appreciate or depreciate in value, capital gains (respectively, losses) accumulate. When stocks are sold, investors pay *taxes* on the realized net capital gains. The taxes are computed as a percentage of the difference between the current market value of the stocks and their tax basis, where the tax basis is the price at which the stocks were bought originally.¹⁰ The percentage is less for long-term capital gains (when stocks have been held for more than a year) than it is for short-term capital gains (when stocks have been held for less than a year).¹¹ Since shares of the same stock could have been bought at different points in time (in different lots), selling one lot of the stock as opposed to another could incur a different amount of tax. In addition to capital gains taxes, investors who are not exempt from taxes owe taxes on the dividends paid on stocks in their portfolios. Those dividends are historically taxed at a higher rate than capital gains, and may eventually be taxed as income, that is, at the investor's personal tax rate. The tax liability of a particular portfolio therefore depends on the timing of the execution of trades, on the tax basis of the portfolio, on the accumulated short-term and long-term capital gains, and on the tax bracket of the investor.

Over two-thirds of marketable portfolio assets in the United States are held by individuals, insurance, and holding companies who pay taxes on their returns. (Exceptions are, for ex-

ample, pension funds, which do not pay taxes year-to-year.) Studies have indicated that taxes are the greatest expense investors face—greater than commissions and investment management fees. To gain some intuition about the effect of taxes on the income of an investor over the investor's lifetime, consider a portfolio that has a capital appreciation of 6.00% per year. After 30 years, \$1,000 invested in that portfolio will turn into $\$1,000 \cdot (1 + 0.06)^{30} = \$5,743.49$. Now suppose that the capital gains are realized each year, and a tax of 35% is paid on the gains (the remainder is reinvested). After 30 years, \$1,000 invested in the portfolio will turn into $\$1,000 \cdot (1 + (1 - 0.35) \cdot 0.06)^{30} = \$3,151.13$, about half of the amount without taxes even when the tax is about one third of the capital gains. In fact, in order to provide the same return as the portfolio with no taxes, the portfolio with annual realized capital gains would need to generate a capital appreciation of 9.23% per year! One can imagine that the same logic would make benchmark tracking and performance measurement very difficult on an after-tax basis.

As investors have become more aware of the dramatic impact of taxes on their returns, there is increasing pressure on portfolio managers to include tax considerations in their portfolio rebalancing decisions and to report after-tax performance. Consequently, the demand for computationally efficient and quantitatively rigorous methods for taking taxes into consideration in portfolio allocation decisions has grown in recent years. The complexity of the problem of incorporating taxes, however, is considerable, both from a theoretical and practical perspective:

1. The presence of tax liabilities changes the interpretation of even fundamental portfolio performance summary measures such as market value and risk. Thus, well-established methods for evaluating portfolio performance on a pretax basis do not work well in the case of tax-aware portfolio optimization. For example, in traditional

portfolio management a loss is associated with risk and is therefore minimized whenever possible. However, in the presence of taxes, losses may be less damaging, because they can be used to offset capital gains and reduce the tax burden of portfolio rebalancing strategies. Benchmarking is also not obvious in the presence of taxes: Two portfolios that have exactly the same current holdings are not equivalent if the holdings have a different tax basis.¹²

2. Tax considerations are too complex to implement in a nonautomated fashion; at the same time, their automatic inclusion in portfolio rebalancing algorithms requires the ability to solve very difficult, large-scale optimization problems.
3. The best approach for portfolio management with tax considerations is optimization problem formulations that look at return forecasts over several time periods (e.g., until the end of the year) before recommending new portfolio weights. However, the latter multiperiod view of the portfolio optimization problem is very difficult to handle computationally—the dimension of the optimization problem, that is, the number of variables and constraints, increases exponentially with the number of time periods under consideration.

We need to emphasize that while many of the techniques described in the previous sections of this entry are widely known, there are no standard practices for tax-aware portfolio management that appear to be established. Different asset management firms interpret tax-aware portfolio allocation and approach the problem differently. To some firms, minimizing turnover,¹³ for example, by investing in index funds, or selecting strategies that minimize the portfolio dividend yield,¹⁴ qualify as tax-aware portfolio strategies. Other asset management firms employ complex optimization algorithms that incorporate tax considerations directly in portfolio rebalancing decisions, so

that they can keep up with the considerable burden of keeping track of thousands of managed accounts and their tax preferences. The fact is, even using simple rules of thumb, such as always selling stocks from the oldest lots after rebalancing the portfolio with classical portfolio optimization routines, can have a positive effect on after-tax portfolio returns. The latter strategy minimizes the likelihood that short-term gains will be incurred, which in turn reduces taxes, because short-term capital gains are taxed at a higher rate than long-term capital gains.

Apelfeld, Fowler, and Gordon (1996) suggest a tax-aware portfolio rebalancing framework that incorporates taxes directly into the portfolio optimization process. The main idea of the approach is to treat different lots of the same stock as different securities, and then penalize for taxes as if they were different transaction costs associated with the sale of each lot. (This means, for example, that Microsoft stock bought on Date 1 is treated as a different security from Microsoft stock bought on Date 2.) Many tax-aware quantitative investment strategies employ versions of this approach, but there are a few issues to beware of when using it in practice:

- The first one is a general problem for all tax-aware approaches when they are used in the context of active portfolio management. For a portfolio manager who handles thousands of different accounts with different tax exposures, it is virtually impossible to pay attention to the tax cost incurred by each individual investor. While the tax-aware method described above minimizes the overall tax burden by reducing the amount of realized short-term sales, it has no provisions for differentiating between investors in different tax brackets because it is difficult to think of each trade as divided between all investors, and adjusted for each individual investor's tax circumstances. This issue is so intractable that in practice it is not really brought under consideration.

- The dimension of the problem can become unmanageable very quickly. For example, a portfolio of 1,000 securities, each of which has 10 different lots, is equivalent to a portfolio of 10,000 securities when each lot is treated as a different security. Every time a new purchase is realized, a new security is added to the portfolio, since a new lot is created. One needs to exercise care and “clean up” lots that have been sold and therefore have holdings of zero each time the portfolio is rebalanced.
- Practitioners typically use factor models for forecasting returns and estimating risk. One of the assumptions when measuring portfolio risk through factor models is that the specific risk of a particular security is uncorrelated with the specific risk of other securities. (The only risk they share is the risk expressed through the factors in the factor model.) This assumption clearly does not hold when different “securities” are in fact different lots of the same stock.

DiBartolomeo (2000) describes a modification to the model used by Northfield Information Service’s portfolio management software that eliminates the last two problems. Instead of treating each lot as a separate security, the software imposes piecewise-linear transaction costs (see Figure 1) where the break points on the horizontal axis correspond to the current size of different lots of the same security. The portfolio rebalancing algorithm goes through several iterations for the portfolio weights, and at each iteration, only the shares in the highest cost basis tax lot can be traded. Other shares of the same stock can be traded in subsequent iterations of the algorithm, with their appropriate tax costs attached.

The approaches we described so far take into consideration the short-term or long-term nature of capital gains, but do not incorporate the ability to offset capital gains and losses accumulated over the year. This is an inherent limitation of single-period portfolio rebalancing approaches and is a strong argument in fa-

vor of adopting more realistic multiperiod portfolio optimization approaches. The rebalancing of the portfolio at each point in time should be made not only by considering the immediate consequences for the market value of the portfolio, but also the opportunity to correct for tax liabilities by realizing other capital gains or losses by the end of the taxable year. The scarce theoretical literature on multiperiod tax-aware portfolio optimization contains some characterizations of optimal portfolio strategies under numerous simplifying assumptions.¹⁵ However, even under such simplifying assumptions, the dimension of the problem grows exponentially with the number of stocks in a portfolio, and it is difficult to come up with computationally viable algorithms for portfolios of realistic size.

MULTIACCOUNT OPTIMIZATION

Portfolio managers who handle multiple accounts face an important practical issue. When individual clients’ portfolios are managed, portfolio managers incorporate their clients’ preferences and constraints. However, on any given trading day, the necessary trades for multiple diverse accounts are pooled and executed simultaneously. Moreover, typically trades may not be crossed, that is, it is not simply permissible to transfer an asset that should be sold on behalf of one client into the account of another client for whom the asset should be bought.¹⁶ The trades should be executed in the market. Thus, each client’s trades implicitly impact the results for the other clients: The market impact of the combined trades may be such that the benefits sought for individual accounts through trading are lost due to increased overall transaction costs. A robust multiaccount management process should ensure accurate accounting and fair distribution of transaction costs among the individual accounts.

One possibility to handle the effect of trading in multiple accounts is to use an iterative

process, in which at each iteration the market impact of the trades in previous iterations is taken into account.¹⁷ More precisely, single clients' accounts are optimized as usual, and once the optimal allocations are obtained, the portfolio manager aggregates the trades and computes the actual marginal transaction costs based on the aggregate level of trading. The portfolio manager then reoptimizes individual accounts using these marginal transaction costs, and aggregates the resulting trades again to compute new marginal transaction costs, and so on. The advantage of this approach is that little needs to be changed in the way individual accounts are typically handled, so the existing single-account optimization and management infrastructure can be reused. The disadvantage is that most generally, this iterative approach does not guarantee a convergence (or its convergence may be slow) to a "fair equilibrium," in which clients' portfolios receive an unbiased treatment with respect to the size and the constraint structure of their accounts.¹⁸ The latter equilibrium is the one that would be attained if all clients traded independently and competitively in the market for liquidity, and it is thus the correct and fair solution to the aggregate trading problem.

An alternative, more comprehensive approach is to optimize trades across all accounts simultaneously. O'Connell, Scherer, and Xu (2006) describe such a model and show that it attains the fair equilibrium we mentioned above.¹⁹ Assume that client k 's utility function is given by u_k and is in the form of a dollar return penalized for risk. Assume also that a transaction cost model τ gives the cost of trading in dollars, and that τ is a convex increasing function.²⁰ Its exact form will depend on the details of how trading is implemented. Let \mathbf{t} be the vector of trades. It will typically have the form $(t_1^+, \dots, t_N^+, t_1^-, \dots, t_N^-)$, that is, it will specify the aggregate buys t_i^+ and the aggregate sells t_i^- for each asset $i=1, \dots, N$, but it may also incorporate information about how the trade could be carried out.²¹

The multiaccount optimization problem can be formulated as

$$\begin{aligned} \max_{\mathbf{w}_1, \dots, \mathbf{w}_K, \mathbf{t}} \quad & E[u_1(\mathbf{w}_1)] + \dots + E[u_K(\mathbf{w}_K)] - \tau(\mathbf{t}) \\ \text{s.t.} \quad & \mathbf{w}_k \in C_k, k = 1, \dots, K \end{aligned}$$

where \mathbf{w}_k is the N -dimensional vector of asset holdings (or weights) of client k , and C_k is the collection of constraints on the portfolio structure of client k . The objective can be interpreted as maximization of net expected utility, that is, as maximization of the expected dollar return penalized for risk and net of transaction costs.

The problem can be simplified by making some reasonable assumptions. For example, it can be assumed that the transaction cost function τ is additive across different assets, that is, that trades in one asset do not influence trading costs in another. In such a case, the trading cost function can be split into more manageable terms, that is,

$$\tau(\mathbf{t}) = \sum_{i=1}^N \tau_i(t_i^+, t_i^-)$$

where $\tau_i(t_i^+, t_i^-)$ is the cost of trading asset i as a function of the aggregate buys and sells of that asset. Splitting the terms $\tau_i(t_i^+, t_i^-)$ further into separate costs of buying and selling, however, is not a reasonable assumption, because simultaneous buying and selling of an asset tends to have an offsetting effect on its price.

To formulate the problem completely, let \mathbf{w}_k^0 be the vector of original holdings (or weights) of client k 's portfolio, \mathbf{w}_k be the vector of decision variables for the optimal holdings (or weights) of client k 's portfolio, and $\eta_{k,i}$ be constants that convert the holdings (or weight) of each asset i in client k 's portfolio $w_{k,i}$ to dollars, that is, $\eta_{k,i}w_{k,i}$ is client k 's dollar holdings of asset i .²² We also introduce new variables \mathbf{w}_k^+ to represent the an upper bound on the weight of each asset client k will buy:

$$w_{k,i} - w_{k,i}^0 \leq w_{k,i}^+, \quad i = 1, \dots, N, k = 1, \dots, K$$

The aggregate amount of asset i bought for all clients can then be computed as

$$t_i^+ = \sum_{k=1}^K \eta_{k,i} \cdot w_{k,i}^+$$

The aggregate amount of asset i sold for all clients can be easily expressed by noticing that the difference between the amounts bought and sold of each asset are exactly equal to the total amount of trades needed to get from the original position $w_{k,i}^0$ to the final position $w_{k,i}$ of that asset.²³

$$t_i^+ - t_i^- = \sum_{k=1}^K \eta_{k,i} \cdot (w_{k,i} - w_{k,i}^0)$$

Here t_i^+ and t_i^- are nonnegative variables.

The multiaccount optimization problem then takes the form

$$\begin{aligned} \max_{\mathbf{w}_1, \dots, \mathbf{w}_K, t^+, t^-} & E[u_1(\mathbf{w}_1)] + \dots + E[u_K(\mathbf{w}_K)] - \sum_{i=1}^N \tau_i(t_i^+, t_i^-) \\ \text{s.t. } & \mathbf{w}_k \in C_k, k = 1, \dots, K \\ & w_{k,i} - w_{k,i}^0 \leq w_{k,i}^+, i = 1, \dots, N, k = 1, \dots, K \\ & t_i^+ = \sum_{k=1}^K \eta_{k,i} w_{k,i}^+, i = 1, \dots, N \\ & t_i^+ - t_i^- = \sum_{k=1}^K \eta_{k,i} \cdot (w_{k,i} - w_{k,i}^0), i = 1, \dots, N \\ & t_i^+ \geq 0, t_i^- \geq 0, w_{k,i}^+ \geq 0, i = 1, \dots, N, k = 1, \dots, K \end{aligned}$$

O'Kinneide, Scherer, and Xu (2006) studied the behavior of the model in simulated experiments with a simple model for the transaction cost function, namely, one in which

$$\tau(t) = \theta \cdot t^\gamma$$

where t is the trade size, and θ and γ are constants satisfying $\theta \geq 0$ and $\gamma \geq 1$.²⁴ θ and γ are specified in advance and calibrated to fit observed trading costs in the market. The transaction costs for each client k can therefore be expressed as

$$\tau_k = \theta \sum_{i=1}^N |w_{k,i} - w_{k,i}^0|^\gamma$$

O'Kinneide, Scherer, and Xu (2006) observed that key portfolio performance measures, such

as the information ratio (IR),²⁵ turnover, and total transaction costs, change under this model relative to the traditional approach. Not surprisingly, the turnover and the net information ratios of the portfolios obtained with *multiaccount optimization* are lower than those obtained with single-account optimization under the assumption that accounts are traded separately, while transaction costs are higher. These results are in fact more realistic, and they are a better representation of the postoptimization performance of multiple client accounts in practice.

ROBUST PARAMETER ESTIMATION

The most commonly used approach for estimating security expected returns, covariances, and other parameters that are inputs to portfolio optimization models is to calculate the sample analogues from historical data. These are sample estimates for the parameters we need. It is important to remember that when we rely on historical data for estimation purposes, we in fact assume that the past provides a good representation of the future.

It is well known, however, that expected returns exhibit significant time variation (referred to as nonstationarity). They are impacted by changes in markets and economic conditions, such as interest rates, the political environment, consumer confidence, and the business cycles of different industry sectors and geographical regions. Consequently, extrapolated historical returns are often poor forecasts of future returns.

Similarly, the covariance matrix is unstable over time. Moreover, sample estimates of covariances for portfolios with thousands of stocks are notoriously unreliable, because we need large data sets to estimate them, and such large data sets of relevant data are difficult to procure. Estimates of the covariance matrix based on factor models are often used to reduce the number of statistical estimates needed from a limited set of data.

In practice, portfolio managers often alter historical estimates of different parameters subjectively or objectively, based on their expectations and forecasting models for future trends. They also use statistical methods for finding estimators that are less sensitive to outliers and other sampling errors, such as Bayesian and shrinkage estimators. A complete review of advanced statistical estimation topics is beyond the scope of this entry. We provide a brief overview of the most widely used concepts.²⁶

Shrinkage is a form of averaging different estimators. The shrinkage estimator typically consists of three components: (1) an estimator with little or no structure (like the sample mean); (2) an estimator with a lot of structure (the shrinkage target); and (3) a coefficient that reflects the shrinkage intensity. Probably the most well-known estimator for expected returns in the financial literature was proposed by Jorion (1986). The shrinkage target in Jorion's model is a vector array with the return on the minimum variance portfolio, and the shrinkage intensity is determined from a specific formula.²⁷ Shrinkage estimators are used for estimates of the covariance matrix of returns as well,²⁸ although equally weighted portfolios of covariance matrix estimators have been shown to be equally effective as shrinkage estimators.²⁹

Bayesian estimation approaches, named after the English mathematician Thomas Bayes, are based on subjective interpretations of the probability that a particular event will occur. A probability distribution, called the prior distribution, is used to represent the investor's knowledge about the probability before any data are observed. After more information is gathered (e.g., data are observed), a formula (known as Bayes' rule) is used to compute the new probability distribution, called the posterior distribution.

In the portfolio parameter estimation context, a posterior distribution of expected returns is derived by combining the forecast from the empirical data with a prior distribution. One of the most well-known examples of the applica-

tion of the Bayesian framework in this context is the Black-Litterman model,³⁰ which produces an estimate of future expected returns by combining the market equilibrium returns (i.e., returns that are derived from pricing models and observable data) with the investor's subjective views. The investor's views are expressed as absolute or relative deviations from the equilibrium together with confidence levels of the views (as measured by the standard deviation of the views).

The ability to incorporate exogenous insight, such as a portfolio manager's opinion, into quantitative forecasting models is important; this insight may be the most valuable input to the model. The Bayesian framework provides a mechanism for forecasting systems to use both important traditional information sources such as proprietary market data and subjective external information sources such as analyst's forecasts.

It is important to realize that regardless of how sophisticated the estimation and forecasting methods are, they are always subject to estimation error. What makes matters worse, however, is that different estimation errors can accumulate over the different activities of the portfolio management process, resulting in large aggregate errors at the final stage. It is therefore critical that the inputs evaluated at each stage are reliable and robust, so that the aggregate impact of estimation errors is minimized.

PORTFOLIO RESAMPLING

Robust parameter estimation is only one part of ensuring that the quantitative portfolio management process as a whole is reliable. It has been observed that portfolio allocation schemes are very sensitive to small changes in the inputs that go into the optimizer. In particular, a well-known study by Black and Litterman³¹ demonstrated that in the case of mean-variance optimization, small changes in the inputs for expected returns had a substantial impact on

the portfolio composition. “Optimal” portfolios constructed under conditions of uncertainty can have extreme or nonintuitive weights for some stocks.

With advances in computational capabilities and new research in the area of optimization under uncertainty, practitioners in recent years have been able to incorporate considerations for uncertainty not only at the estimation, but also at the portfolio optimization stage. Methods for taking into consideration inaccuracies in the inputs to the portfolio optimization problem include simulation (resampling) and robust optimization. We explain *portfolio resampling* in this section, and robust portfolio optimization in the following section.

A logical approach to making portfolio allocation more robust with respect to changes in the input parameters is to generate different scenarios for the values these parameters can take, and to find weights that remain stable for small changes in the input parameters. This method is referred to as *portfolio resampling*.³² To illustrate the resampling technique, we explain how it is applied to portfolio mean-variance optimization.

Suppose that we have initial estimates for the expected stock returns, $\hat{\boldsymbol{\mu}}$, and covariance matrix, $\hat{\boldsymbol{\Sigma}}$, for the N stocks in the portfolio. (We use “hat” to denote a statistical estimate.)

1. We simulate S samples of N returns from a multivariate normal distribution with mean $\hat{\boldsymbol{\mu}}$ and covariance matrix $\hat{\boldsymbol{\Sigma}}$.
2. We use the S samples generated in (1) to compute S new estimates of vectors of expected returns $\hat{\boldsymbol{\mu}}_1, \dots, \hat{\boldsymbol{\mu}}_S$ and covariance matrices $\hat{\boldsymbol{\Sigma}}_1, \dots, \hat{\boldsymbol{\Sigma}}_S$.
3. We solve S portfolio optimization problems, one for each estimated pair of expected returns and covariances $(\hat{\boldsymbol{\mu}}_s, \hat{\boldsymbol{\Sigma}}_s)$, and save the weights for the N stocks in a vector array $\mathbf{w}^{(s)}$, where $s = 1, \dots, S$. (The optimization problem itself could be any of the standard mean-variance formulations: maximize expected return subject to constraints on

risk, minimize risk subject to constraints on the expected return, or maximize the utility function.)

4. To find the final portfolio weights, we average out the weight for each stock over the S weights found for that stock in each of the S optimization problems. In other words,

$$\mathbf{w} = \frac{1}{S} \sum_{s=1}^S \mathbf{w}^{(s)}$$

For example, stock i in the portfolio has final weight

$$w_i = \frac{w_i^{(1)} + \dots + w_i^{(S)}}{S}$$

5. Perhaps even more valuable than the average estimate of the weights obtained from the simulation and optimization iterations is the probability distribution we obtain for the portfolio weights. If we plot the weights for each stock obtained over the S iterations, $w_i^{(1)}, \dots, w_i^{(S)}$, we can get a sense for how variable this stock weight is in the portfolio. A large standard deviation computed from the distribution of portfolio weight i will be an indication that the original portfolio weight was not very precise due to estimation error.

An important question, of course, is how large is “large enough.” Do we have evidence that the portfolios we obtained through resampling are statistically different from one another? We can evaluate that by using a test statistic. For example, it can be shown that the test statistic

$$d(\mathbf{w}^*, \mathbf{w}) = (\mathbf{w}^* - \mathbf{w})' \boldsymbol{\Sigma} (\mathbf{w}^* - \mathbf{w})$$

follows a chi-square (χ^2) distribution with degrees of freedom equal to the number of securities in the portfolio. If the value of this statistic is statistically “large,” then there will be evidence that the portfolio weights \mathbf{w}^* and \mathbf{w} are statistically different. This is an important insight for the portfolio manager, and its applications extend beyond just resampling. Let us provide some intuition as to why.

Suppose that we are considering rebalancing our current portfolio. Given our forecasts of expected returns and risk, we could calculate a set of new portfolios through the resampling procedure. Using the test statistic above, we determine whether the new set of portfolio weights is statistically different from our current weights and, therefore, whether it would be worthwhile to rebalance or not. If we decide that it is worthwhile to rebalance, we could choose any of the resampled portfolios that are statistically different from our current portfolio. Which one should we choose? A natural choice would be to select the portfolio that would lead to the lowest transaction costs. The idea of determining statistically equivalent portfolios, therefore, has much wider implications than the ones illustrated in the context of resampling.

Resampling has its drawbacks:

- Since the resampled portfolio is calculated through a simulation procedure in which a portfolio optimization problem needs to be solved at each step, the approach is computationally cumbersome, especially for large portfolios. There is a trade-off between the number of resampling steps and the accuracy of estimation of the effect of errors on the portfolio composition.
- Due to the averaging in the calculation of the final portfolio weights, it is highly likely that all stocks will end up with nonzero weights. This has implications for the amount of transaction costs that will be incurred if the final portfolio is to be attained. One possibility is to include constraints that limit both the turnover and the number of stocks with nonzero weights. As we saw earlier, however, the formulation of such constraints adds another level of complexity to the optimization problem and will slow down the resampling procedure.
- Since the averaging process happens *after* the optimization problems are solved, the final weights may not actually satisfy some of the constraints in the optimization formulation.

In general, only convex (such as linear) constraints are guaranteed to be satisfied by the averaged final weights. Turnover constraints, for example, may not be satisfied. This is a serious limitation of the resampling approach for practical applications.

Despite these limitations, resampling has advantages and presents a good alternative to using only point estimates of inputs to the optimization problem.

ROBUST PORTFOLIO OPTIMIZATION

Another way in which uncertainty about the inputs can be modeled is by incorporating it directly into the optimization process. *Robust optimization* is an intuitive and efficient way to deal with uncertainty. Robust portfolio optimization does not use the traditional forecasts, such as expected returns and covariances, but rather uncertainty sets containing these point estimates. An example of such an uncertainty set is a confidence interval around the forecast for each expected return (“alpha”). This uncertainty shape looks like a “box” in the space of the input parameters. (See Figure 2(A).) We can also formulate advanced uncertainty sets that incorporate more knowledge about the estimation error. For instance, a widely used uncertainty set is the ellipsoidal uncertainty set, which takes into consideration the covariance structure of the estimation errors. (See Figure 2(B).) We will see examples of both uncertainty sets in this section.

The robust optimization procedure for portfolio allocation is as follows. First, we specify the uncertainty sets around the input parameters in the problem. Then, we ask what the optimal portfolio allocation is when the input parameters take the worst possible value inside these uncertainty sets. In effect, we solve an inner problem that determines the worst possible realization of the uncertain parameters over

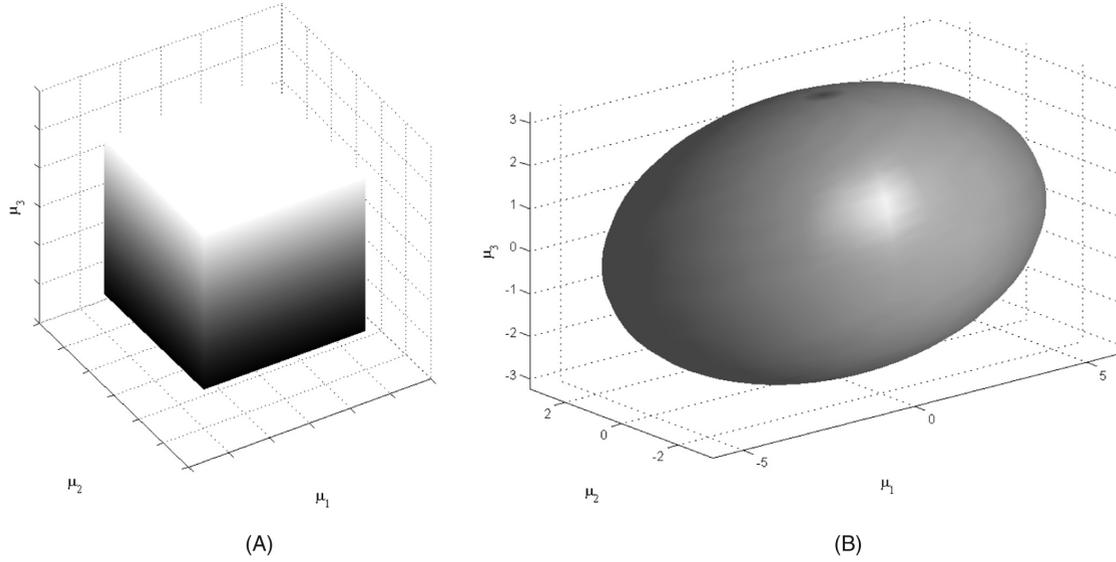

Figure 2 (A) Box Uncertainty Set in Three Dimensions; (B) Ellipsoidal Uncertainty Set in Three Dimensions

the uncertainty set before we solve the original problem of optimal portfolio allocation.

Let us give a specific example of how the robust optimization framework can be applied in the portfolio optimization context. Consider the utility function formulation of the mean-variance portfolio allocation problem:

$$\begin{aligned} \max_{\mathbf{w}} \quad & \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{1} = 1 \end{aligned}$$

Suppose that we have estimates $\hat{\boldsymbol{\mu}}$ and $\hat{\boldsymbol{\Sigma}}$ of the vector of expected returns and the covariance matrix. Instead of the estimate $\hat{\boldsymbol{\mu}}$, however, we will consider a set of vectors $\boldsymbol{\mu}$ that are “close” to $\hat{\boldsymbol{\mu}}$. We define the box uncertainty set

$$U_{\delta}(\hat{\boldsymbol{\mu}}) = \{\boldsymbol{\mu} \mid |\mu_i - \hat{\mu}_i| \leq \delta_i, i = 1, \dots, N\}$$

In words, the set $U_{\delta}(\hat{\boldsymbol{\mu}})$ contains all vectors $\boldsymbol{\mu} = (\mu_1, \dots, \mu_N)$ such that each component μ_i is in the interval $[\hat{\mu}_i - \delta_i, \hat{\mu}_i + \delta_i]$. We then solve the following problem:

$$\max_{\mathbf{w}} \left\{ \min_{\boldsymbol{\mu} \in U_{\delta}(\hat{\boldsymbol{\mu}})} \{\boldsymbol{\mu}'\mathbf{w}\} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \right\} \quad \text{s.t.} \quad \mathbf{w}'\mathbf{1} = 1$$

This is called the robust counterpart of the original problem. It is a max-min problem that searches for the optimal portfolio weights when the estimates of the uncertain returns take their worst-case values within the prespecified uncertainty set in the sense that the value of the objective function is the worst it can be over all possible values for the expected returns in the uncertainty set.

It can be shown³³ that the max-min problem above is equivalent to the following problem

$$\begin{aligned} \max_{\mathbf{w}} \quad & \mathbf{w}'\boldsymbol{\mu} - \delta'|\mathbf{w}| - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{1} = 1 \end{aligned}$$

where $|\mathbf{w}|$ denotes the absolute value of the entries of the vector of weights \mathbf{w} . To gain some intuition, notice that if the weight of stock i in the portfolio is negative, the worst-case expected return for stock i is $\mu_i + \delta_i$ (we lose the largest amount possible). If the weight of stock i in the portfolio is positive, then the worst-case expected return for stock i is $\mu_i - \delta_i$ (we gain the smallest amount possible). Observe that $\mu_i w_i - \delta_i |w_i|$ equals $(\mu_i - \delta_i) w_i$ if the weight w_i is positive and $(\mu_i + \delta_i) w_i$ if the weight w_i is

negative. Hence, the mathematical expression in the objective agrees with our intuition: It minimizes the worst-case expected portfolio return. In this robust version of the mean-variance formulation, stocks whose mean return estimates are less accurate (i.e., have a larger estimation error δ_i) are therefore penalized in the objective function and will tend to have a smaller weight in the optimal portfolio allocation.

This optimization problem has the same computational complexity as the nonrobust mean-variance formulation—namely, it can be stated as a quadratic optimization problem. The latter can be achieved by using a standard trick that allows us to get rid of the absolute values for the weights. The idea is to introduce an N -dimensional vector of additional variables ψ to replace the absolute values $|w|$, and to write an equivalent version of the optimization problem,

$$\begin{aligned} \max_{\mathbf{w}, \psi} \quad & \mathbf{w}'\hat{\boldsymbol{\mu}} - \delta'\boldsymbol{\psi} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{1} = 1 \\ & \psi_i \geq w_i; \psi_i \geq -w_i, i = 1, \dots, N \end{aligned}$$

Therefore, incorporating considerations about the uncertainty in the estimates of the expected returns in this example has virtually no computational cost.

We can view the effect of this particular “robustification” of the mean-variance portfolio optimization formulation in two different ways. On the one hand, we can see that the values of the expected returns for the different stocks have been adjusted downward in the objective function of the optimization problem. The robust optimization model “shrinks” the expected return of stocks with large estimation error, that is, in this case the robust formulation is related to statistical shrinkage methods, which we introduced earlier in this entry. On the other hand, we can interpret the additional term in the objective function as a “risk-like” term that represents penalty for estimation error. The size of the penalty is determined by the investor’s aversion to estimation risk and is reflected in the magnitude of the deltas.

More complicated specifications for uncertainty sets have more involved mathematical representations, but can still be selected so that they preserve an easy computational structure for the robust optimization problem. For example, we can use the ellipsoidal uncertainty set from Figure 2(B), which can be expressed mathematically as

$$U_\delta(\hat{\boldsymbol{\mu}}) = \{ \boldsymbol{\mu} \mid (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}})' \boldsymbol{\Sigma}_\mu^{-1} (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}}) \leq \delta^2 \}.$$

Here $\boldsymbol{\Sigma}_\mu$ is the covariance matrix of estimation errors for the vector of expected returns $\boldsymbol{\mu}$. This uncertainty set represents the requirement that the sum of squares (scaled by the inverse of the covariance matrix of estimation errors) between all elements in the set and the point estimates $\hat{\mu}_1, \hat{\mu}_2, \dots, \hat{\mu}_N$ can be no larger than δ^2 . We note that this uncertainty set cannot be interpreted as individual confidence intervals around each point estimate. Instead, it captures the idea of a joint confidence region. In practical applications, the covariance matrix of estimation errors is often assumed to be diagonal. In the latter case, the set contains all vectors of expected returns that are within a certain number of standard deviations from the point estimate of the vector of expected returns, and the resulting robust portfolio optimization problem would protect the investor if the vector of expected returns is within that range.

It can be shown that the robust counterpart of the mean-variance portfolio optimization problem with an ellipsoidal uncertainty set for the expected return estimates is the following optimization problem formulation:

$$\begin{aligned} \max_{\mathbf{w}} \quad & \mathbf{w}'\boldsymbol{\mu} - \lambda \cdot \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} - \delta \cdot \sqrt{\mathbf{w}'\boldsymbol{\Sigma}_\mu\mathbf{w}} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{1} = 1 \end{aligned}$$

This is a second-order cone optimization problem and requires specialized software to solve, but the methods for solving it are very efficient.

Similarly to the case of the robust counterpart with a box uncertainty set, we can interpret the extra term in the objective function ($\delta \cdot \sqrt{\mathbf{w}'\boldsymbol{\Sigma}_\mu\mathbf{w}}$) as the penalty for estimation risk,

where δ incorporates the degree of the investor's aversion to estimation risk. Note, by the way, that the covariance matrix in the estimation error penalty term, Σ_{μ} , is not necessarily the same as the covariance matrix of returns Σ . In fact, it is not immediately obvious how Σ_{μ} can be estimated from data. Σ_{μ} is the covariance matrix of the errors in the estimation of the expected (average) returns. Thus, if a portfolio manager forecasts 5% active return over the next time period, but gets 1%, the manager cannot argue that there was a 4% error in the expected return—the actual error would consist of both an estimation error in the expected return and the inherent volatility in actual realized returns. In fact, critics of the approach such as Lee, Stefek, and Zhelenyak (2006) have argued that the realized returns typically have large stochastic components that dwarf the expected returns, and hence estimating Σ_{μ} from data is very hard, if not impossible.

Several approximate methods for estimating Σ_{μ} have been found to work well in practice. For example, Stubbs and Vance (2005) observe that simpler estimation approaches, such as using just the diagonal matrix containing the variances of the estimates (as opposed to the complete error covariance matrix), often provide most of the benefit in robust portfolio optimization. In addition, standard approaches for estimating expected returns, such as Bayesian statistics and regression-based methods, can produce estimates for the estimation error covariance matrix in the process of generating the estimates themselves.³⁴

Among practitioners, the notion of robust portfolio optimization is often equated with the robust mean-variance model we discussed in this section, with the box or the ellipsoidal uncertainty sets for the expected stock returns. While robust optimization applications often involve one form or another of this model, the actual scope of robust optimization can be much broader. We note that the term *robust optimization* refers to the technique of incorporating information about uncertainty sets for the pa-

rameters in the optimization model, and not to the specific definitions of uncertainty sets or the choice of parameters to model as uncertain. For example, we can use the robust optimization methodology to incorporate considerations for uncertainty in the estimate of the covariance matrix in addition to the uncertainty in expected returns, and obtain a different robust portfolio allocation formulation. Robust optimization can be applied also to portfolio allocation models that are different from the mean-variance framework, such as Sharpe ratio optimization and value-at-risk optimization.³⁵ Finally, robust optimization has the potential to provide a computationally efficient way to handle portfolio optimization over multiple stages—a problem for which so far there have been few satisfactory solutions.³⁶ There are numerous useful robust formulations, but a complete review is beyond the scope of this entry.³⁷

Is implementing robust optimization formulations worthwhile? Some tests with simulated and real market data indicate that robust optimization, when inaccuracy is assumed in the expected return estimates, outperforms classical mean-variance optimization in terms of total excess return a large percentage (70–80%) of the time (see, for example, Ceria and Stubbs, 2006). Other tests have not been as conclusive (see, for example, Lee, Stefek, and Zhelenyak, 2006). The factor that accounts for much of the difference is how the uncertainty in parameters is modeled. Therefore, finding a suitable degree of robustness and appropriate definitions of uncertainty sets can have a significant impact on portfolio performance.

Independent tests by practitioners and academics using both simulated and market data appear to confirm that robust optimization generally results in more stable portfolio weights, that is, that it eliminates the extreme corner solutions resulting from traditional mean-variance optimization. This fact has implications for portfolio rebalancing in the presence of transaction costs and taxes, as transaction costs

and taxes can add substantial expenses when the portfolio is rebalanced. Depending on the particular robust formulations employed, robust mean-variance optimization also appears to improve worst-case portfolio performance and results in smoother and more consistent portfolio returns. Finally, by preventing large swings in positions, robust optimization typically makes better use of the turnover budget and risk constraints.

Robust optimization, however, is not a panacea. By using robust portfolio optimization formulations, investors are likely to trade off the optimality of their portfolio allocation in cases in which nature behaves as they predicted for protection against the risk of inaccurate estimation. Therefore, investors using the technique should not expect to do better than classical portfolio optimization when estimation errors have little impact, or when typical scenarios occur. They should, however, expect insurance in scenarios in which their estimates deviate from the actual realized values by up to the amount they have prespecified in the modeling process.

KEY POINTS

- Commonly used constraints in practice include long-only (no short-selling) constraints, turnover constraints, holding constraints, risk factor constraints, and tracking error constraints. These constraints can be handled in a straightforward way by the same type of optimization algorithms used for solving the classical mean-variance portfolio allocation problem.
- Minimum holding constraints, transaction size constraints, cardinality constraints, and round-lot constraints are also widely used in practice, but their nature is such that they require binary and integer modeling, which necessitates the use of mixed-integer and other specialized optimization solvers.
- Transaction costs can easily be incorporated in standard portfolio allocation models. Typical functions for representing transaction

costs include linear, piecewise linear, and quadratic.

- Taxes can have a dramatic effect on portfolio returns; however, it is difficult to incorporate them into the classical portfolio optimization framework. Their importance to the individual investor is a strong argument for taking a multiperiod view of investments, but the computational burden of multiperiod portfolio optimization formulations with taxes is extremely high.
- For investment managers who handle multiple accounts, increased transaction costs because of the market impact of simultaneous trades can be an important practical issue and should be taken into consideration when individual clients' portfolio allocation decisions are made to ensure fairness across accounts.
- As the use of quantitative techniques has become widespread in the investment industry, the consideration of estimation risk and model risk has grown in importance. Methods for robust statistical estimation of parameters include shrinkage and Bayesian techniques.
- Portfolio resampling is a technique that uses simulation to generate multiple scenarios for possible values of the input parameters in the portfolio optimization problem and aims to determine portfolio weights that remain stable with respect to small changes in model parameters.
- Robust portfolio optimization incorporates uncertainty directly into the optimization process. The uncertain parameters in the optimization problem are assumed to vary in prespecified uncertainty sets that are selected subjectively or based on data.

NOTES

1. See Chapter 1 in Maginn and Tuttle (1990).
2. Multiperiod portfolio optimization models are still rarely used in practice, not because the value of multiperiod modeling is

questioned, but because such models are often too intractable from a computational perspective.

3. As the term intuitively implies, the ADV measures the total amount of a given asset traded in a day on average, where the average is taken over a prespecified time period.
4. Another computationally tractable situation for minimizing CVaR is when the data are normally distributed. In that case, minimizing CVaR is equivalent to minimizing the standard deviation of the portfolio.
5. See Chapters 8 and 9 in Pachamanova and Fabozzi (2010) for a more detailed explanation of CVaR and a derivation of the optimization formulation.
6. Versions of this model have been suggested in Pogue (1970), Schreiner (1980), Adcock and Meade (1994), Lobo, Fazel, and Boyd (2000), and Mitchell and Braun (2004).
7. Here we are thinking of w_i as the portfolio weights, but in fact it may be more intuitive to think of the transaction costs as a percentage of amount traded. It is easy to go back and forth between portfolio weights and portfolio amounts by simply multiplying w_i by the total amount in the portfolio. In fact, we can switch the whole portfolio optimization formulation around and write it in terms of allocation of dollars, instead of weights. We just need to replace the vector of weights \mathbf{w} by a vector \mathbf{x} of dollar holdings.
8. See, for example, Bertsimas, Darnell, and Soucy (1999).
9. As we explained earlier, this constraint can be written in an equivalent, more optimization solver-friendly form, namely,

$$y_i \geq w_i - w_{0,i}$$

$$y_i \geq -(w_i - w_{0,i})$$
10. The computation of the tax basis is different for stocks and bonds. For bonds, there are special tax rules, and the original price is not the tax basis.
11. The exact rates vary depending on the current version of the tax code, but the main idea behind the preferential treatment of long-term gains to short-term gains is to encourage long-term capital investments and fund entrepreneurial activity.
12. See Stein (1998).
13. See Apelfeld, Fowler, and Gordon (1996) who show that a manager can outperform on an after-tax basis with high turnover as well, as long as the turnover does not result in net capital gains taxes. (There are other issues with high turnover, however, such as higher transaction costs that may result in a lower overall portfolio return.)
14. Dividends are taxed as regular income, i.e., at a higher rate than capital gains, so minimizing the portfolio dividend yield should theoretically result in a lower tax burden for the investor.
15. See Constantinides (1983), Dammon and Spatt (1996), and Dammon, Spatt, and Zhang (2001 and 2004).
16. The Securities and Exchange Commission (SEC) in general prohibits cross-trading but does provide exemptions if prior to the execution of the cross trade the asset manager can demonstrate to the SEC that a particular cross trade benefits both parties. Similarly, Section 406(b)(3) of the Employee Retirement Income Security Act of 1974 (ERISA) forbids cross-trading, but there is new cross-trading exemption in Section 408(b)(19) adopted in the Pension Protection Act of 2006.
17. Khodadadi, Tutuncu, and Zangari (2006).
18. The iterative procedure is known to converge to the equilibrium, however, under special conditions. See O’Cinneide, Scherer, and Xu (2006).
19. The issue of considering transaction costs in multiaccount optimization has been discussed by others as well. See, for example, Bertsimas, Darnell, and Soucy (1999).
20. As we mentioned earlier in this entry, realistic transaction costs are in fact described by

- nonlinear functions, because costs per share traded typically increase with the size of the trade due to market impact.
21. For example, if asset i is a euro-pound forward, then a trade in that asset can also be implemented as a euro-dollar forward plus a dollar-forward, so there will be two additional assets in the aggregate trade vector \mathbf{t} .
 22. Note that $\eta_{k,i}$ equals 1 if $w_{k,i}$ is the actual dollar holdings.
 23. Note that, similarly to \mathbf{w}_k^+ , we could introduce additional sell variables \mathbf{w}_k^- , but this is not necessary. By expressing aggregate sales through aggregate buys and total trades, we reduce the dimension of the optimization problem, because there are fewer decision variables. This would make a difference for the speed of obtaining a solution, especially in the case of large portfolios and complicated representation of transaction costs.
 24. Note that $\gamma = 1$ defines linear transaction costs. For linear transaction costs, multi-account optimization produces the same allocation as single-account optimization, because linear transaction costs assume that an increased aggregate amount of trading does not have an impact on prices.
 25. The information ratio is the ratio of (annualized) portfolio residual return (alpha) to (annualized) portfolio residual risk, where risk is defined as standard deviation.
 26. For further details, see Chapters 6, 7, and 8 in Fabozzi, Kolm, Pachamanova, and Focardi (2007).
 27. See Chapter 8 in Fabozzi, Kolm, Pachamanova, and Focardi (2007).
 28. See, for example, Ledoit and Wolf (2003).
 29. For an overview of such models, see Disatnik and Benninga (2007).
 30. For a step-by-step description of the Black-Litterman model, see Chapter 8 in Fabozzi, Kolm, Pachamanova, and Focardi (2007).
 31. See Black and Litterman (1992).
 32. See Michaud (1998), Jorion (1992), and Scherer (2002).
 33. For derivation, see, for example, Chapter 12 in Fabozzi, Kolm, Pachamanova, and Focardi (2007) or Chapter 9 in Pachamanova and Fabozzi (2010).
 34. For a more in-depth coverage of the topic of estimating input parameters for robust optimization formulations, see Chapter 12 in Fabozzi, Kolm, Pachamanova, and Focardi (2007).
 35. See, for example, Goldfarb and Iyengar (2003) and Natarajan, Pachamanova, and Sim (2008).
 36. See Ben-Tal, Margalit, and Nemirovski (2000) and Bertsimas and Pachamanova (2008).
 37. For further details, see Fabozzi, Kolm, Pachamanova, and Focardi (2007).

Basics of Quantitative Equity Investing

PAUL BUKOWSKI, CFA, FCAS

Executive President, Head of Equities, Hartford Investment Management

Abstract: Quantitative equity investing is one method used by investors to identify attractive stocks and gain a competitive advantage. In contrast to fundamental investors who focus on a single company at a time, quantitative investors focus on stock characteristics. Quantitative investors look for sources of information or company characteristics that help to explain why one stock outperforms another stock. They assemble a group of characteristics into a unique stock selection model, which is the core of the quantitative investment process. The quantitative investment process can be divided into three main phases: research, portfolio construction, and monitoring. During the research phase, the stock selection model is created. During the portfolio construction phase, the quantitative investor uses the stock selection model to create a live portfolio. Finally, during the monitoring phase, the quantitative investor makes sure the portfolio is performing as expected and modifies it as needed. While quantitative investing can be very different from fundamental investing, they are complementary and combined can lead to a more well-rounded overall investment approach.

The goal of this entry is to provide the basics of *quantitative equity investing* and an explanation of the quantitative investing process. More specifically, I focus on the following three questions. First, how do quantitative and *fundamental equity* investors differ? Second, what are the core steps in a quantitative equity investment process? Finally, what are the basic building blocks used by quantitative equity investors?

In answering these questions, I will pull back the curtain on the quantitative equity investment process, showing how it is similar to many other approaches, all searching for the best stocks. Where it differs is in the creation of a repeatable process that uses several key cri-

teria to find the most attractive companies—its *stock selection model*. Finally, some of the most common techniques used by quantitative equity investors are covered.

It is important to understand that this entry is dedicated to a traditional quantitative equity investing approach. There are many other types of investing that are quantitative in nature (e.g., high-frequency trading, statistical arbitrage, etc.), which will not be covered.

EQUITY INVESTING

Investing can take many forms, but it starts with an investor assigning a value to a security.

Figure 1 The Value of a Stock Comes from Multiple Information Sources

Whether this value exceeds or is less than the current market price usually determines whether the investor will buy or sell the security. In the case of equities, the investor often seeks to understand the specific company under consideration, the broader economic environment, and the interplay between the two. This encompasses a wide range of information for the investor to consider as displayed in Figure 1. How this information is used differentiates the quantitative from the fundamental investor.

FUNDAMENTAL VS. QUANTITATIVE INVESTOR

Let's start with a basic question. How do portfolio managers select stocks from a broad universe of 1,000 or more companies?

Fundamental managers start with a basic company screen. For instance, they may first look for companies that satisfy conditions such as a price-earnings (P/E) ratio that is less than 15, earnings growth greater than 10%, and profit margins in excess of 20%. Filtering by those *characteristics* may result in, say, 200 potential candidates. Next, portfolio managers in consultation with their group of stock analysts will

spend the majority of their time thoroughly reviewing each of the potential candidates to arrive at the best 50 to 100 stocks for their portfolio. Quantitative managers, in contrast, spend the bulk of their time determining the characteristics for the initial stock screen, their stock selection model. They will look for five or more unique characteristics that are good at identifying the most attractive 200 stocks of the universe. Quantitative managers will then purchase all 200 stocks for their portfolio.

So let's expand on how these two investors—fundamental and quantitative—differ. Figure 2 details the main attributes of the two approaches discussed further below.

Focus: Company versus Characteristic: The fundamental investor's primary analysis is on a single company at a time, while the quantitative investor's primary analysis is on a single characteristic at a time. For example, a fundamental investor may analyze a health care company to assess whether a company's sales prospects look strong and whether this stronger sales growth is reflected in the company's current stock price. A quantitative investor may also invest in a company based on its sales growth, but

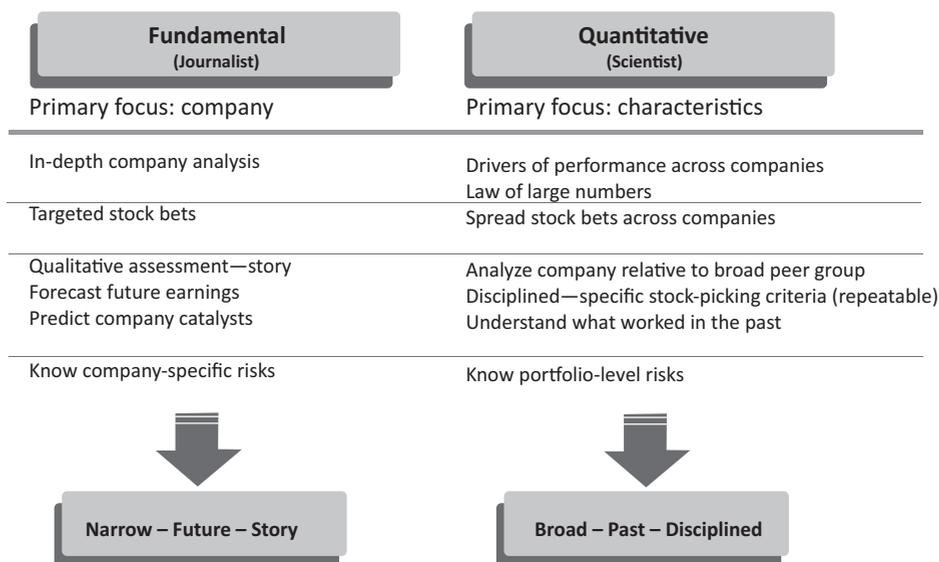

Figure 2 Fundamental vs. Quantitative Investor: Viewing Information

will start by assessing the sales growth characteristic. The quantitative investor will determine whether stocks within the group, health care companies, with higher sales growth also have higher stock returns. If they do, then the quantitative investor will buy health care stocks with higher sales growth. In the end, both types of investors may buy a stock due to its good sales prospects, but both come at the decision from a different point of view.

Narrow vs. Broad: Fundamental investors focus their attention narrowly on a small group of stocks. They cover fewer companies since they make more in-depth reviews of each company. Fundamental investors immerse themselves in the company, studying everything from financial information, to new products, to meeting management. Ideally, they are searching for exploitable differences between their detailed assessment of the company's value and the market's perception of that value. In contrast, quantitative investors focus more broadly. Rather than reviewing one company at a time, they look across a large group of companies. Quan-

titative investors focus on what separates companies from one another; they search for pieces of information (characteristics) that they can use to exploit differences between securities. Since they are dealing with a great deal of data from a large number of companies, they employ quantitative techniques to quickly sift through the information.

Position Concentration/Size of Bets: Another difference in the two approaches is the size of the positions within a portfolio; they tend to be larger for a fundamental investor and smaller for a quantitative investor. Fundamental investors perform in-depth company analysis so they will have greater conviction in taking larger positions in their selected stocks. Quantitative investors perform in-depth analysis across a group of companies, so they will tend to spread their bets across this larger group of companies.

Risk Perspective: The fundamental investor sees risk at the company level while the quantitative investor is more focused at the portfolio level. Fundamental investors will review the risk to both their forecasts and catalysts for the company. They understand

Fundamental	Quantitative
Small portfolio	Large portfolio
Larger positions	Smaller positions
Performance at sector/company level	Performance at characteristic level
Emphasize stock-specific risk	Diversify stock-specific risk

Figure 3 Fundamental vs. Quantitative Investor: Process Differences

how a changing macro picture can impact their valuation of the company. In contrast, the quantitative investor's broader view relates to understanding the risks across the portfolio. They understand if there are risk characteristics in their portfolio that are different from their chosen stock selection model. For example, a quantitative investor who does not believe growth prospects matter to a company's stock performance would want to investigate if the model had the investor buying many very high- or low-growth companies.

Past vs. Future: Finally, the fundamental investor often places greater emphasis on the future prospects of the company while the quantitative investor studies the company's past. Fundamental investors tend to paint a picture of the company's future; they will craft a story around the company and its prospects; and they will look for catalysts generating future growth for a company. They rely on their ability to predict changes in a company. In contrast, the quantitative investor places more emphasis on the past, using what is known or has been reported by a company. Quantitative investors rely on historical accounting data as well as historical strategy simulations, or backtests, to search for the best company characteristics to select stocks. For instance, they will look at whether technology companies with stronger profitability have performed better than those without, or whether retail companies with stronger inventory controls have performed better than those without.

Quantitative investors are looking for stock picking criteria that can be tested and incorporated into a stock selection model.

In the end, we have two types of investors viewing information, often the same information, quite differently. The fundamental investor is a journalist focused on crafting a unique story of a company's future prospects and predicting the potential for gain in the company's stock. The quantitative investor is a scientist, broadly focused, relying on historical information to differentiate across all companies, using statistical techniques to create a stock selection model.

These two investors can and often do create different portfolios based on their different approaches as shown in Figure 3. Fundamental investors are more focused, with higher conviction in their stocks resulting in fewer, larger positions in their portfolios. Quantitative investors, reviewing a large group of companies, generally take a large number of smaller positions in their portfolio. Fundamental investors are investing in a stock (or sector) and therefore are most concerned with how much each of their stocks (or sectors) is contributing to performance. Quantitative investors are investing in a characteristic and how well it differentiates stocks. They want to know how each of their characteristics is contributing to performance. Finally, fundamental investors' detailed view into the company allows them to understand the intrinsic risk of each investment they make—the potential stumbling blocks for each company. Quantitative investors' goal is to

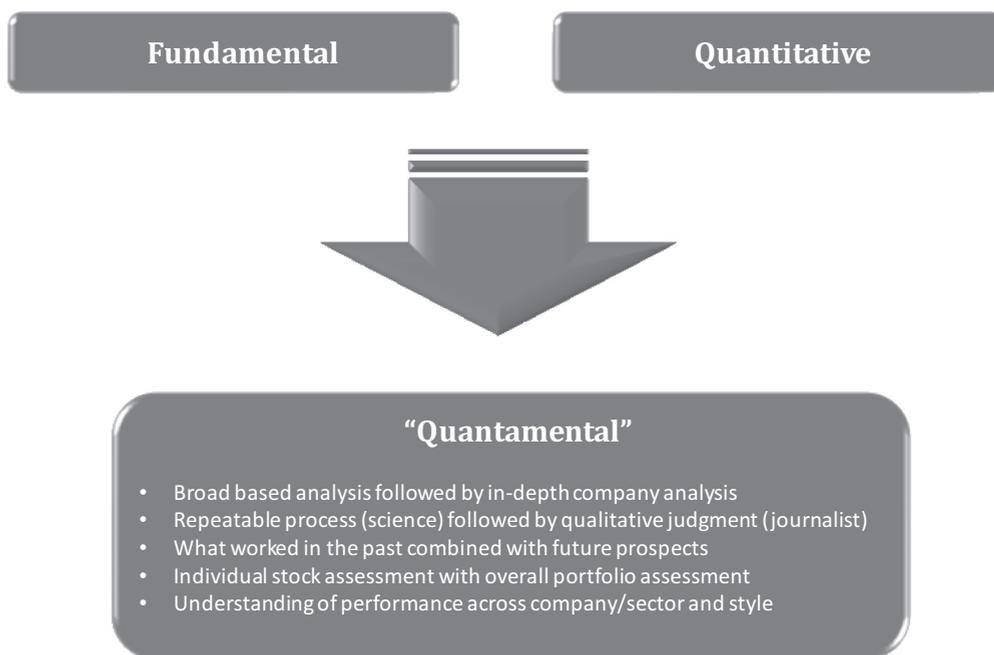

Figure 4 Benefits of a Combined Fundamental and Quantitative Approach

understand specific characteristics across a broad universe of stocks. They look at risks across their entire portfolio, attempting to diversify away any firm-specific risks ancillary to their strategy.

Now that you understand the basic differences between the two approaches, it might also be clear how using both investment styles can be very appealing. As Figure 4 shows, the two styles are quite complementary in nature and can provide a robust, well-rounded view of a company or portfolio. Combining the two approaches provides the following benefits:

- **Breadth and depth.** In-depth analysis across a large group of stocks selecting the best subset of companies, which is followed by in-depth review of the small subset of attractive companies.
- **Facts balanced with human insight.** The scientific approach reviewing large amounts of data across many companies complemented by personal judgment at the company level.
- **Past and future perspective.** A detailed historical review of companies combined with a

review of future potential prospects of a company.

- **Full risk analysis.** A broad look at risk both within each company owned and across the entire portfolio.
- **Clear portfolio performance.** A thorough understanding of which companies, sectors, and characteristics are driving a portfolio's performance.

In fact, over the years, the defining line between the two approaches has been blurring. Some have coined a term for this joint process: "quantamental." Many investment managers are combining both approaches in one investment process, which is why whether you are a fundamental or quantitative investor, it is important to understand both perspectives.

Given our preceding discussion, the distinction between the quantitative and fundamental approaches should now be better appreciated. In the remainder of this entry we restrict our focus to the quantitative equity investment process, addressing the last two topics listed at the beginning of this entry: the core steps in a

quantitative equity investment process and some of the basic building blocks used by quantitative investors.

THE QUANTITATIVE STOCK SELECTION MODEL

Before diving into the details of the quantitative investment process, let's look at what is at its core—the stock selection model. As explained in the previous section, the quantitative investment approach is rooted in understanding what separates strong-performing stocks from weak-performing stocks.¹ The quantitative investor looks for sources of information or company characteristics (often referred to as factors or signals)² that help to explain why one stock outperforms another stock. They assemble these characteristics into a stock selection model, which can be run daily to provide an updated view on every stock in their investment universe.

The stock selection model is at the heart of the quantitative process. To build the model, the quantitative investor will look throughout history and see what characteristics drive performance differences between stocks in a group such as a universe (i.e., small cap, small-cap value, and large-cap growth) or a sector (i.e., technology, financials, materials).

The quantitative investor's typical stock selection methodology is buying stocks with the most attractive attributes and not investing in (or shorting, if permitted by investment guidelines) stocks with the least attractive attributes. For instance, let's suppose retail stocks that have the highest profitability tend to have higher stock returns than those with the lowest profitability. In this case, if a retail stock had strong profitability, there is a greater chance a portfolio manager would purchase it. Profitability is just one characteristic of a company. The quantitative investor will look at a large number of characteristics, from 25 to over 100, to include in the stock selection model. In the

Figure 5 Sample Stock Selection Model for the Retail Sector

end, they will narrow their final model to a few characteristics that are best at locating performance differences among stocks in a particular universe or sector.

Figure 5 is an example of a stock selection model for the retail sector. If a stock has good margins and positive earnings growth, sell-side analysts like it, solid inventory management and is attractively valued, especially as pertains to earnings, then the quantitative investor would buy it. And if it did not have these characteristics, a quantitative investor would not own it, sell it, or short it. This example is for a retail sector; a quantitative investor could also have different models to select stocks in the bank sector or utilities sector or among small-cap value stocks.

So how does a quantitative investor create and use the stock selection model? A good analogy is a professional golfer. Like a quantitative investor, golfers create a model of their game. First, golfers analyze all elements of their basic swing from backswing to follow through. They then alter their swing to different conditions (high winds, rain, cold), and different

course types (links, woodlands, fast greens). Next, golfers put their model into action. While they are golfing, they make mental notes about what is and isn't working to help enhance their game. Could they tweak their swing? What has been effective under the current weather conditions? How are they playing this type of course?

Overall, the golfers' process is much like quantitative investors' process. They create a model, implement it, and then monitor it, assessing their ability to shoot below par. Like professional golfers who go to the driving range for countless hours to perfect their swing, quantitative investors will spend countless hours perfecting their model, understanding how it works under many different market (weather/course) conditions.

With that analogy in mind, we now turn to the entire quantitative investment process.

THE OVERALL QUANTITATIVE INVESTMENT PROCESS

The quantitative process can be divided into the following three main phases (shown in Figure 6):

- Research
- Portfolio construction
- Monitoring

During the *research* phase, the stock selection model is created. During the *portfolio construction* phase, the quantitative investor

“productionalizes” the stock selection model or gets it ready to invest in a live portfolio. Finally, during the *monitoring* phase, the quantitative investor makes sure the portfolio is performing as expected.

RESEARCH

Let's start with the research phase since it is the basic building block of the quantitative process. It is where the fact-finding mission begins. This is similar to when the golfer spends countless hours at the driving range perfecting his (or her) swing. In this phase, the quantitative investor determines what aspects of a company make its stock attractive or unattractive. The research phase begins by the quantitative investors testing all the characteristics they have at their disposal, and it finishes with assembling the chosen characteristics into a stock selection model (see Figure 7).

1. **Characteristic Testing.** First, quantitative investors determine which characteristics are good at differentiating strong-performing from weak-performing stocks. Initially, the quantitative investor segments the stocks. This could be by sector, such as consumer discretionary; industry, such as consumer electronics; or a universe, such as small-cap value stocks. Once the stocks have been grouped, each of the characteristics is tested to see if it can delineate the strong-performing stocks from the weak-performing stocks.

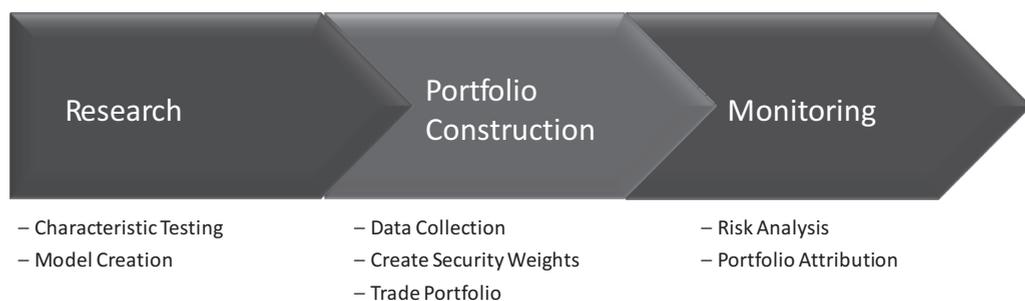

Figure 6 Three Core Phases of the Quantitative Equity Investment Process

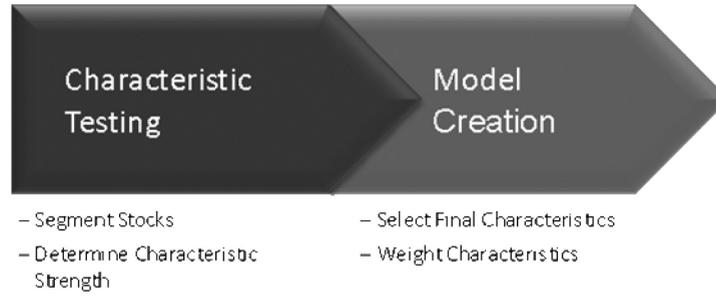

Figure 7 Two Core Steps in the Research Phase of the Quantitative Equity Investment Process

2. *Model Creation.* Second, quantitative investors select the final characteristics that are best at picking the most attractive stocks. Then they weight each characteristic in the stock selection model—determining which characteristics should be more relied upon when picking stocks, or if they all should be treated equally.

looks at historical information over 20 years or more in order to cover multiple market cycles. While testing, many performance metrics are reviewed to get an expansive view of a characteristic’s ability to differentiate stocks. These metrics span the return category, risk category, and other metrics as outlined in Figure 8. Using an array of metrics, quantitative investors are better able to confirm a characteristic’s consistency. They make sure that the selected characteristics score well on more than a single metric. Before continuing with the research process, let’s review a few of the more commonly used metrics.

During the research phase, the quantitative investor tries to get a broad picture of a characteristic, making sure it performs well under a diverse set of conditions and performance measures. For testing, the quantitative investor

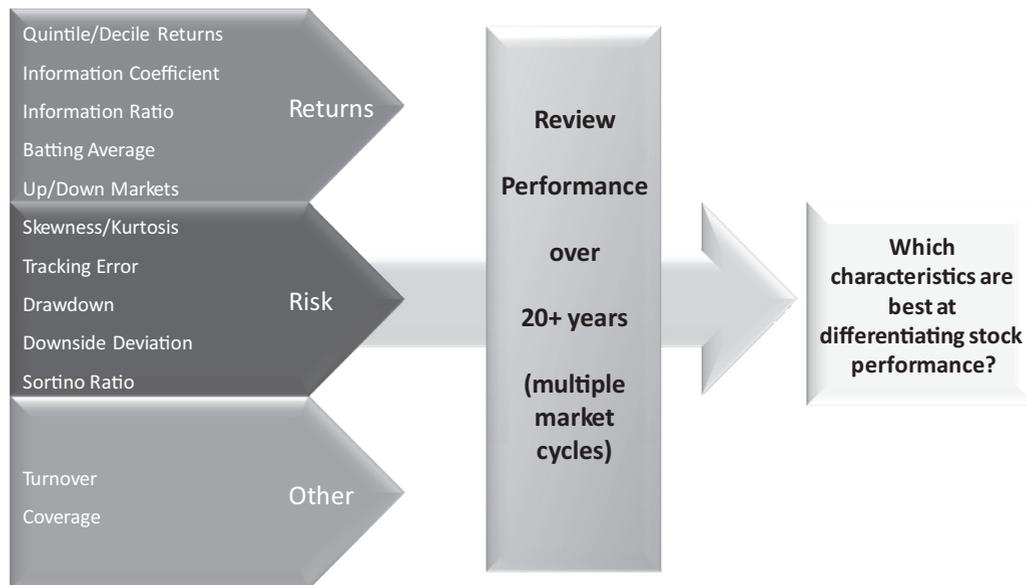

Figure 8 Characteristic Testing in the Research Phase

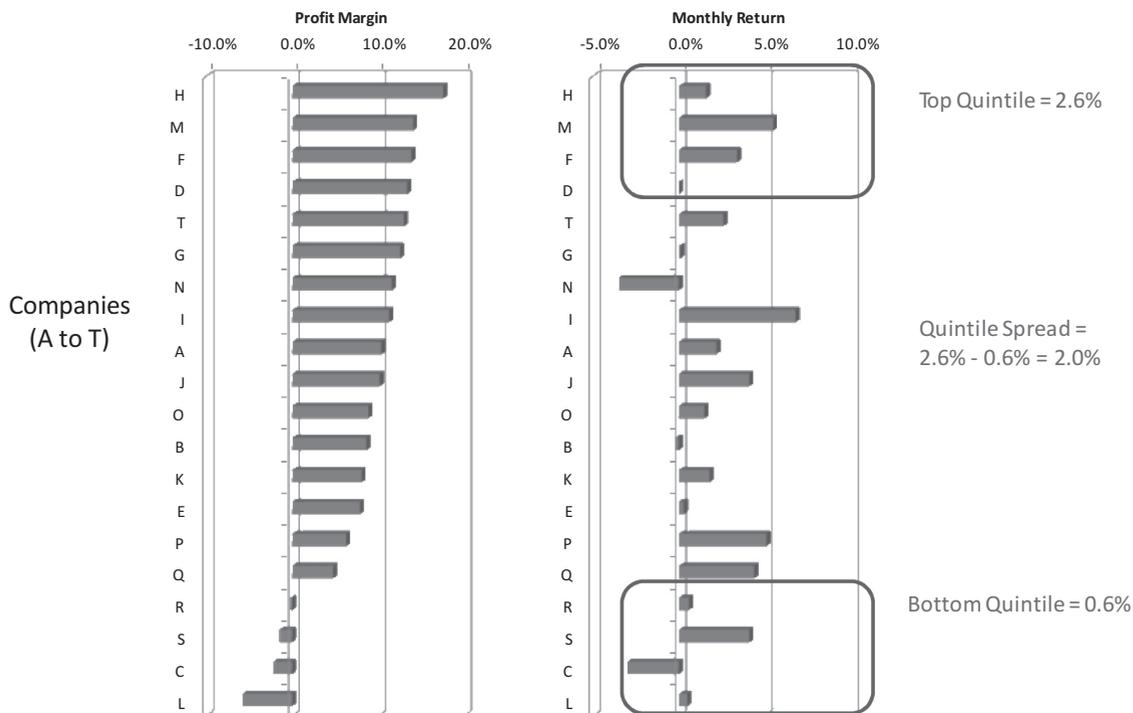

Figure 9 Determining the Characteristic's Quintile Spread

Characteristic Testing: Key Quantitative Research Metrics

In this section we will review quintile returns and information coefficients, which measure whether a characteristic can differentiate between winning and losing stocks. Although profitability was chosen for the examples, other characteristics such as sales growth, P/E ratio, or asset turnover also could have been chosen.

Quintile Returns

The *quintile return* is already prevalent across most research publications, but is gaining popularity in more and more mainstream publications such as the *Wall Street Journal*, *Barron's*, and the like. Quintile returns measure how well a characteristic differentiates stocks. In essence, the stocks that are being reviewed are segmented into five groups (quintiles) and then are tested to determine if the companies in the group with the best attributes (top quintile) out-

perform the group with the least desirable attributes (bottom quintile).

Figure 9 provides an example. In this example, we start with 20 companies that we refer to as A through T. The first step—the left-hand side of the exhibit—is to order the 20 companies by profitability from highest to lowest. In the second step, this ordered list is divided into five groups, creating a most profitable group (top quintile) down to the least profitable group (bottom quintile). The top and bottom quintile groups are boxed on the right-hand chart of the figure. Finally, the performance of the top quintile is compared to the bottom quintile.

As Figure 9 shows, the stocks with highest profitability (top quintile) returned 2.6% while the stocks with the lowest profitability (bottom quintile) returned only 0.6%. So the top quintile stocks outperformed the bottom quintile stocks by 2.0%, meaning for this month, the most profitable companies outperformed the least profitable companies by 2.0%. This is commonly

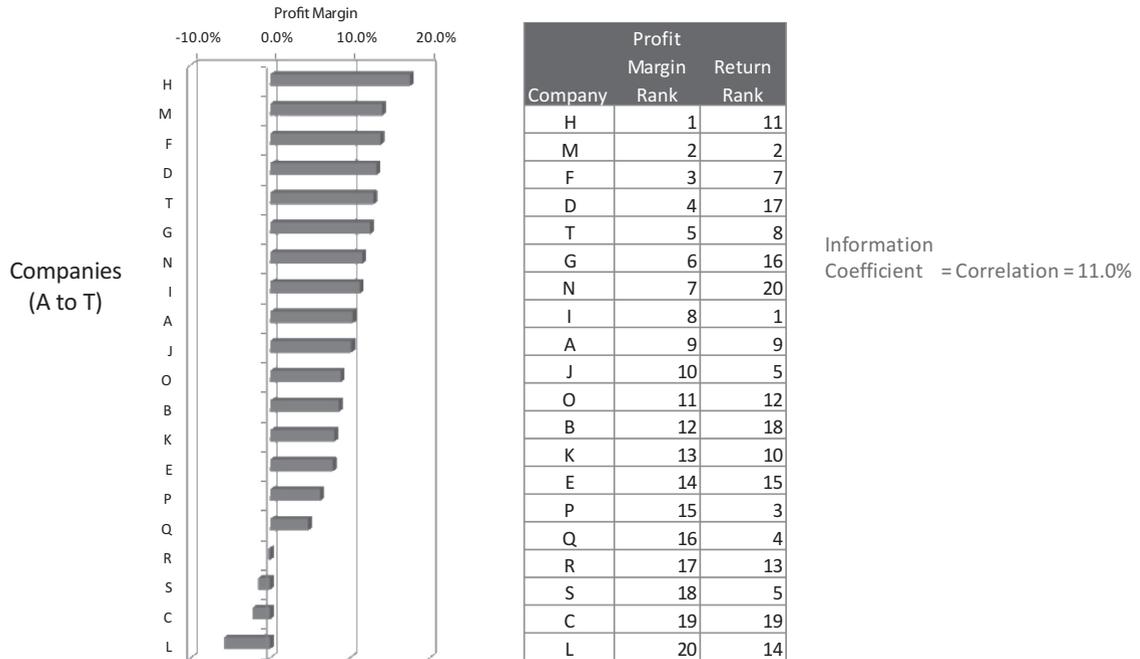

Figure 10 Determining the Characteristic's Information Coefficient

referred to as the characteristic's *quintile return* or quintile spread. The higher the quintile spread, the more attractive the characteristic is.

Information Coefficient

Another common metric used for determining if a characteristic is good at separating the strong- from the weak-performing stocks is the *information coefficient* (IC). It does so by measuring the correlation between a stock's characteristic (i.e., profitability) and its return. The major difference between the IC and quintile return is that the IC looks across all of the stocks, while the quintile return only focuses on the best and worst stocks, ignoring those stocks in the middle. The IC is more concerned with differentiating performance across all stocks rather than the extremes.

The calculation of the IC is detailed in Figure 10. Similar to assessing the quintile return, the sort ordering of the companies based on profitability is done first. However, the next

step is different. In the second step, each stock is ranked on both profitability and return. The most profitable company is assigned a rank of 1 all the way down to the least profitable company, which is assigned a rank of 20. Likewise for stock returns: The highest returning stock is assigned a rank of 1 down to the lowest returning stock receiving a rank of 20. In the third step, the rank of the company's profitability is correlated with the rank of the company's return. The correlation of the two ranks is the IC, which is 11% as shown in Figure 10. The higher the correlation (i.e., IC), the more likely companies with higher profitability also have higher returns and the more effective the characteristic.

When is it better to employ an IC over a quintile spread? IC is a better metric when a quantitative investor is considering owning a greater number of stocks in the portfolio. The reason is that the IC looks at the relationships across all of the stocks in the group. The quintile return is better suited for more concentrated bets in

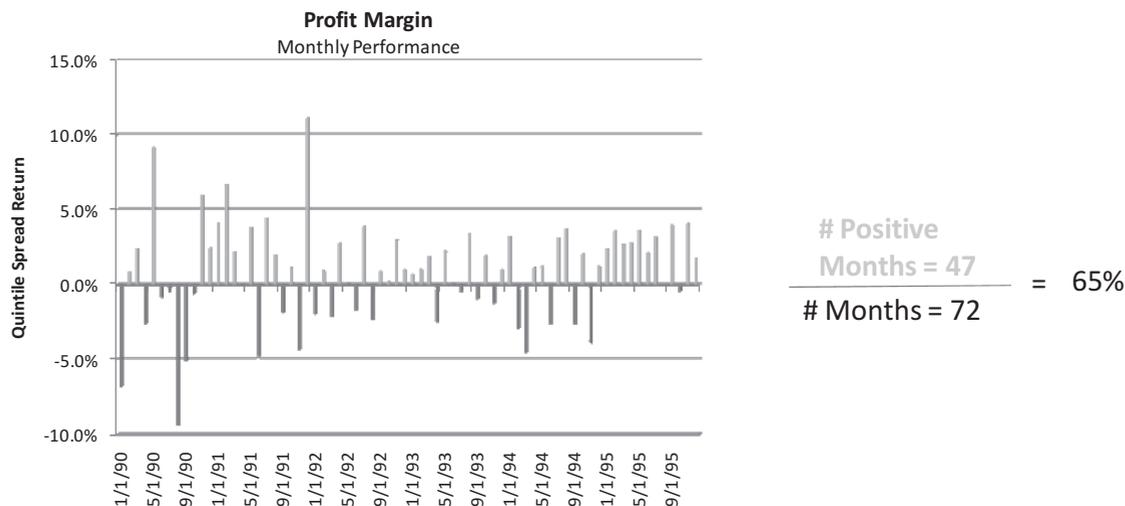

Figure 11 Determining the Characteristic's Batting Average

fewer stocks as it places a greater emphasis on measuring the few stocks at the extremes.

The last two examples reviewed how a characteristic (profitability) was able to explain the next month's return for a group of stocks. In both cases it looked effective—a quintile return of 2.0% and an IC of 11%. However, in practice, it is also necessary to assess whether the characteristic was effective for not only one month, but over decades of investing encompassing multiple market cycles. To that end, during the research process a quantitative investor will look at the average quintile returns or ICs over an extended period of up to 20 years or more. When looking at these longer time series, quantitative investors use additional metrics to understand the characteristic's effectiveness.

Characteristic Testing: Key Measures of Consistency

Two commonly used measures of consistency are batting average and information ratio.

Batting Average

Batting average is a straightforward metric. In baseball a player's batting average is the number of hits divided by the number of times at bat. A similar metric is used in investing.

Batting average is the number of positive performance months (hits) divided by the number of total months (at bats). The higher the batting average, the more consistently the characteristic generates positive performance.

As Figure 11 displays, to arrive at the batting average we take the number of months the quintile return was positive divided by the number of months tested. In our example, in 47 of the 72 months profitability was effective, resulting in a positive return. This translates to a batting average of 65%, which is quite high. Imagine walking into a casino in Las Vegas where you have a 65% chance of winning every bet. That casino would not be in business very long with you at the table.

Information Ratio

Information ratio is also used to measure consistency. This measure is defined as the average return of a characteristic divided by its volatility—basically a measure of return per unit of risk or risk reward ratio. For volatility, quantitative investors use *tracking error*, which is the standard deviation of excess returns.

Figure 12 demonstrates the calculation of the information ratio. In this example, there are two characteristics. Which one should be selected?

Figure 12 Determining the Characteristic's Information Ratio

Based only on returns, we would choose characteristic 2 since it has a higher excess return (3.0%) than characteristic 1 (2.0%). However, as we can see in the figure, characteristic 2 also has much larger swings in performance than characteristic 1 and therefore more risk. The higher risk of characteristic 2 is confirmed by its high tracking error of 12.0%, three times greater than characteristic 1's tracking error of 4.0%. Characteristic 1 looks much better on a risk-adjusted basis with an information ratio of 0.50 (2.0%/4.0%) or twice characteristic 2's information ratio of 0.25 (3.0%/12.0%). So even though characteristic 1 has a lower return than characteristic 2, it also has much less risk, making it preferred since investors are rewarded more for the risk they are taking.

Model Creation

After reviewing and selecting the best characteristics, the quantitative investor then needs to assemble them into a stock selection model. This step of the research process is called model creation. It usually involves two main components:

1. Ascertaining whether the characteristics selected are not measuring the same effect (i.e., are not highly correlated).
2. Assigning weights to the selected characteristics, potentially placing greater emphasis on those in which the quantitative investor has stronger convictions.

Let us begin by discussing the first component in model creation: measuring *correlation*. When including characteristics in a stock selection model, the quantitative investor does not want to include two characteristics that have very similar performance since they may be measuring similar aspects of the company. In these cases, quantitative managers could be potentially doubling their position in a stock for the same reason. For instance, stocks with a historically high sales growth may perform similarly to stocks with high expected growth in the future, or stocks with strong gross margins may perform similarly to stocks with strong profit margins. In either case, we would not include both similar characteristics.

An example is provided in Figure 13, which shows the cumulative quintile spread return over 10 years for three characteristics (which we have labeled A, B, and C). Characteristic A did the best at differentiating the winners from losers—the stocks it liked outperformed the stocks it did not like by almost 10% over the 10-year period. Characteristic B was next with a return slightly greater than 8%, and characteristic C was the lowest with an almost 4% cumulative 10-year return. Given that all three characteristics have good performance, which two should the quantitative investor retain in the model?

Although characteristics A and B are better at differentiating winners from losers than characteristic C, A's return pattern looks very

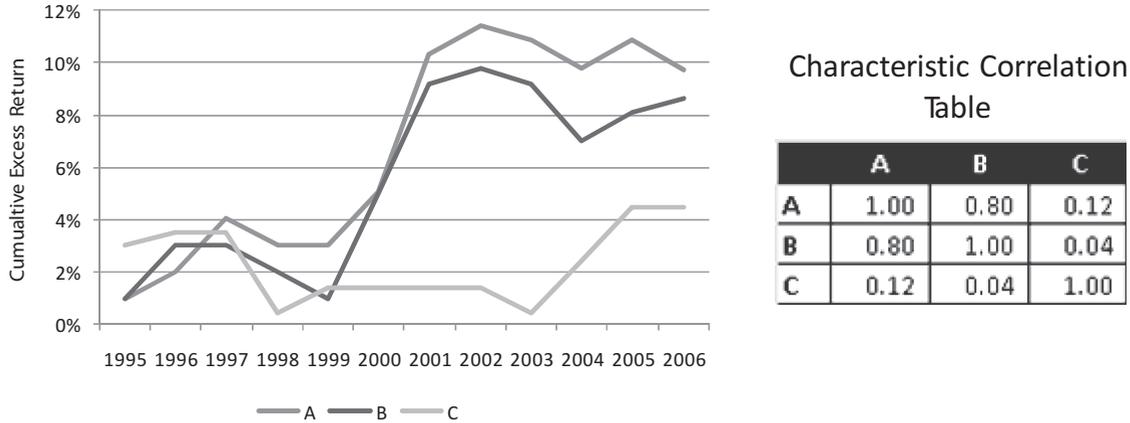

Figure 13 Model Creation: Correlation Review / Table 1 Characteristic Correlations

similar to B's. This is confirmed by Table 1 where characteristics A and B have a correlation of 0.80. Since a correlation of 1.00 means their returns move in lockstep, a correlation of 0.80 indicates they are very similar. Rather than keeping both A and B and potentially doubling our positions from similar characteristics, it would be best to keep either A or B and combine the characteristic retained with C. Even though characteristic C is the worst performing of the three, for the stock selection model C provides a good uncorrelated source of performance.

Once the characteristics to select stocks are identified, quantitative investors are ready to determine the importance or weight of each

characteristic. They must decide whether all characteristics should have the same weight or whether better characteristics should have greater weight in the stock selection model.

There are many ways to determine the weights of the characteristics. We can simply equal weight them or use some other process such as creating an algorithm, performing regressions, or optimizing. Figure 14 shows how a typical stock selection model is created. In this step, the selected characteristics are combined to determine a target for each stock whether it be a return forecast, rank, or a position size.

Once the combination of characteristics for the model is selected, the quantitative investor determines their weights and then reviews the

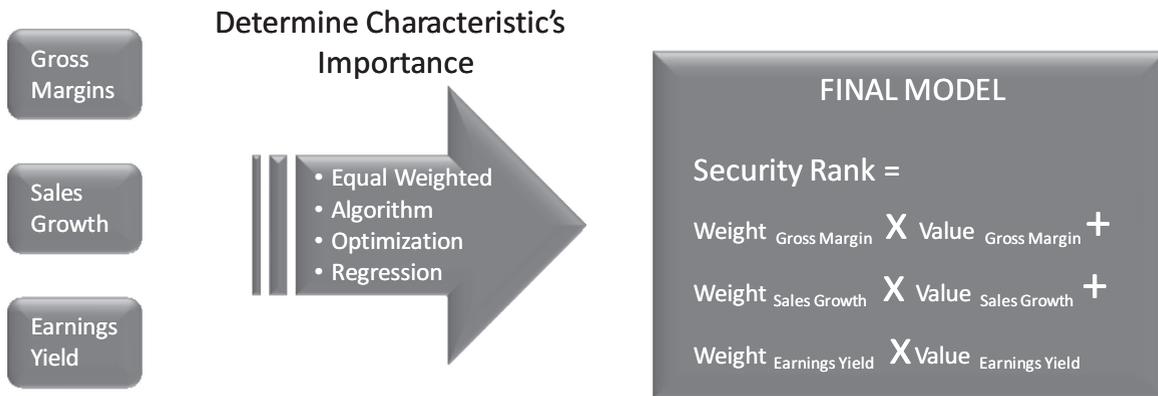

Figure 14 Stock Selection Model: Characteristic Weightings

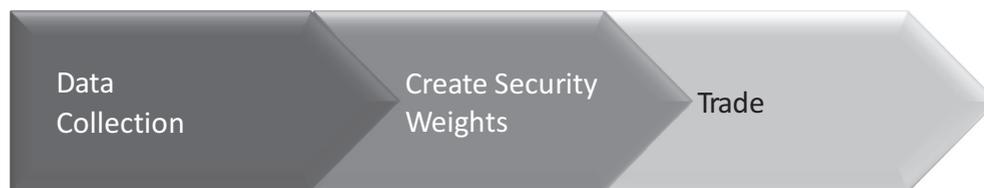

Figure 15 Three Main Steps of the Portfolio Construction Phase

model. Model review is similar to reviewing a single characteristic. The model is looked at from many perspectives, calculating all of the metrics described in Figure 8. The quantitative investor would look at how the top-quintile stocks of the model perform versus the bottom and look at information coefficients of the stock selection model over time. In addition, how much trading or turnover the stock selection model creates is reviewed or if there are any biases in the stock selections (e.g., too many small-cap stocks, or a reliance on high- or low-beta stocks). In practice, the review is much more extensive, covering many more metrics. If the stock selection model does not hold up under this final review, then the quantitative investor will need to change the stock selection model to eliminate the undesirable effects.

PORTFOLIO CONSTRUCTION

In the second phase of the investment process, the quantitative investor uses the stock selection model to buy stocks. It is in this phase that the quantitative investor puts the model into production. Returning to our golfer analogy, this is when they travel to the course to play a round of golf.

During the portfolio construction phase, the model is ready to create a daily portfolio. This phase consists of three main steps as shown in Figure 15 and described below.

Step 1: Collect data. Data are collected on a nightly basis, making sure the data are correct and do not contain any errors.

Step 2: Create security weights. New data are used to both select the stocks that should be

purchased for the portfolio as well as to specify how large its position should be.

Step 3: Trade. The stock selection model that has incorporated the most current information is used for trading.

Data Collection

As Figure 16 shows, data come from many different sources, such as a company's fundamental, pricing, economic, and other data (specialized data sources). All of these data are updated nightly, so it is important to have robust systems and processes established to handle large amounts of data, clean the data (check for errors), and process it in a timely fashion. The quantitative investor seeks to have everything ready to trade at the market opening.

Creating Security Weights

After the data are collected and verified, the next step is running all of the updated company information through the stock selection model. This will create final positions for every stock in the screened universe. In this step, each stock is ranked using the stock selection model, with the better scoring companies making it into the portfolio.

Figure 17 provides a simplified example of this, showing a stock selection model with three characteristics: gross margins, sales growth, and earnings yield (i.e., earnings-to-price ratio; the higher the ratio, the more attractively priced the stock is). From the example, Company ABC is in the top 10% of companies based on gross margin, in the top 30% in sales growth, and average on earnings yield. Company ABC

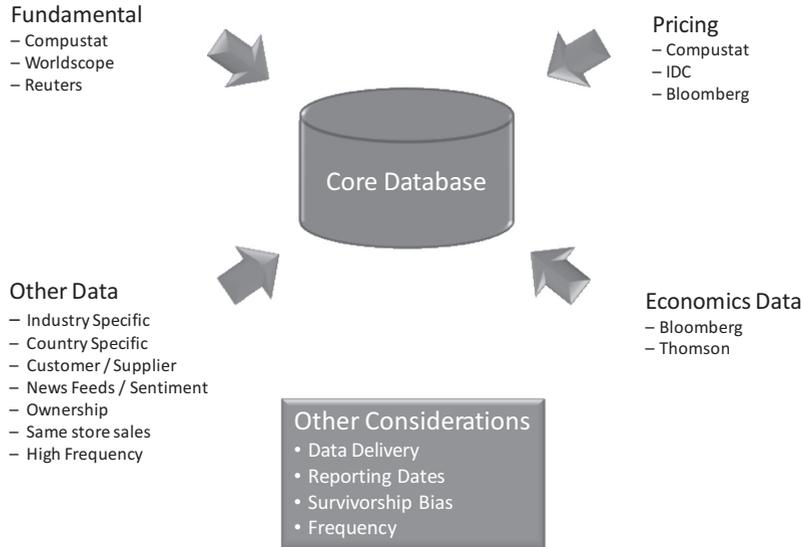

Figure 16 Data Collection Step of the Portfolio Construction Phase

may represent a company finding a profitable market and growing into it, and the rest of the market has not caught on to its prospects, so it is still valued like an average stock. In this case, the stock rates favorably by the stock selection model and would be purchased. The other stock, the stock of Company XYZ, is not as fa-

vorable and either would not be held in the portfolio or, if permitted, could be shorted. Although Company XYZ also has good margins, its growth is slowing and it is relatively expensive compared to its earnings. The company could be one that had a profitable niche, but its niche may be shrinking as sales are dwindling.

Figure 17 Creating Security Weights Step of the Portfolio Construction Phase

Furthermore, the investment community has not discounted the slowing growth and hence the stock is still expensive.

Trade

The final step in the portfolio construction process is to trade into the new positions chosen by the stock selection model. While many investment approaches trade regularly, even daily, quantitative investors tend not to. Quantitative investors tend to trade monthly or longer. They may wait for the views from their stock selection model to change significantly from their current portfolio before trading into the new views.

MONITORING

The third and final phase in the quantitative equity investment process is monitoring performance and risk. This step is important to check if any hidden biases are embedded in the portfolio and that the portfolio is performing in line with expectations. Returning one last time to our golfer analogy, this is when the golfer is making mental notes as to what is and isn't working during the round to improve his or her game in the future. This step can be broken into two activities: risk management and performance attribution.

Risk Management

In *risk management*, the main emphasis is on making sure that the quantitative investor is buying companies consistent with the stock selection model. Returning to the retail model discussed earlier in this entry, the model liked companies with good profit margins but had no view on the company's beta. So the quantitative investor would want to make sure that the companies included in the portfolio have high profit margins but average beta. If the portfolio started to include high-beta stocks, the quantitative investor would want to make adjustments to the process to eliminate this high-beta

bias. There are many types of risk management software and techniques that can be used to detect any hidden risks embedded in the portfolio and provide ways to remedy those identified.

Another aspect of risk management is to make sure that the portfolio's risk level is consistent with the modeling phase. The quantitative investor wants to ensure that the tracking error is not too high or low relative to expectations. Again, risk management techniques and software can be used to monitor tracking error and sources of tracking error, and to remedy any deviations from expectations.

Performance Attribution

Performance attribution is critical in ensuring that the actual live portfolio's performance is coming from the characteristics in the stock selection model and is in line with performance expected during the modeling stage. Performance attribution is like monitoring a car's gas mileage: If the gas mileage begins to dip below what the driver expects, or what it is known to be, then the driver would want to look under the car's hood. Similarly, if the stock selection model is not producing the desired results, or the results have changed, then the quantitative investor would need to look under the hood of the stock selection model. If performance is not being generated from the selected characteristics, then the quantitative manager would want to check out the model in more detail. One possibility is that another characteristic is canceling the desired characteristics, or the model should be providing more weight to the desired characteristic.

The monitoring phase is critical in making sure that the stock selection model is being implemented as expected.

CURRENT TRENDS

Let's look at some recent trends in the quantitative investment industry.

Many quantitative equity investors are looking for additional sources of alpha by using

alternative data sources to help select stocks. One notable source is industry-specific data (e.g., banking, airlines, and retail). Additionally, quantitative investors are turning to the Internet to better understand news flows for companies through Web-based search engines. Furthermore, quantitative investors are using more conditioning models. Conditioning occurs when two characteristics are combined rather than choosing them side by side in a stock selection model. Traditional models would look for companies that have either attractive margins or growth. With conditioning models, companies that have both attractive margins and growth are sought.

Dynamic modeling is gaining renewed popularity. It consists of timing characteristics, determining when they should enter or leave a stock selection model based on business cycle analysis, technical market indicators, or other information. For instance, during recessionary periods, a quantitative investor may want companies with strong profitability, while in expansionary periods companies with good growth prospects are sought. A stock selection model would contain profitability when the economy is entering a recession, and then include the growth characteristic once it felt that the economy is moving into an expansionary period. This is an example of how quantitative investors are bringing more personal judgment to the process, similar to fundamental investors.

Finally, with the advent of high-frequency trading and more advanced trading analytics, many quantitative investors are reviewing how best to implement their stock selection models. Some characteristics such as earnings surprise may have short-lived alpha prospects, so quantitative investors would want to trade into these stocks more quickly. Other characteristics are longer term in nature, such as valuation metrics, so investors would not have to trade into companies with attractive valuations as quickly. Furthermore, trading costs are being measured with greater granularity, allowing quantitative investors to measure transaction cost and incor-

porate these better estimates into their research modeling phase.

KEY POINTS

- Investing begins with processing many different types of information to find the most attractively priced assets. Fundamental and quantitative investors differ in their approach to the available information. The fundamental investor's primary focus is on a single company at a time, while the quantitative investor's primary focus is on a single characteristic at a time.
- Quantitative and fundamental approaches are complementary. By combining the two approaches you can obtain a more well-rounded investment process including breadth and depth in analysis, facts based on human judgment, a past and future perspective of a company, and a more well-rounded view of risk and performance of the portfolio.
- The quantitative equity investment process is made up of three phases: research, portfolio construction, and monitoring. During the research phase, the stock selection model is created. During the portfolio construction phase, the quantitative investor "productionalizes" the stock selection model or gets it ready to invest in a live portfolio. Finally, during the monitoring phase, the quantitative investor makes sure the portfolio is performing as expected.
- At the heart of the quantitative equity investment process is the stock selection model. The model includes those characteristics that are best at delineating the highest from lowest returning stocks. Models can be created for industries, sectors, or styles.
- Two common metrics used to judge a characteristic's effectiveness are quintile returns and information coefficients. Two more metrics used to understand the consistency of a characteristic's performance over time are batting average and information ratio.

- During the portfolio construction phase, data are collected from multiple sources and run through the investor's stock selection model to arrive at a list of buy and sell candidates. The buy candidates will have the strongest characteristic values in the investor's stock selection model, and the sell candidates the weakest characteristic values.
- The monitoring phase is when the investor assures that the performance in the portfolio is consistent with expectations. During this phase, the investor will make sure there are no hidden bets in the portfolio and that the characteristics in the stock selection model are performing as expected.

NOTES

1. Throughout the entry we discuss whether characteristics can separate a stock with strong future returns from one with weak future returns. Many times reference will be made to a "strong" characteristic that can differentiate the strong- from weak-performing stocks.
2. In this entry, the term "characteristic" means the attributes that differentiate companies. Quantitative investors often refer to these same characteristics as factors or signals which they typically use in their stock selection model.

Quantitative Equity Portfolio Management

ANDREW ALFORD, PhD

Managing Director, Quantitative Investment Strategies, Goldman Sachs Asset Management

ROBERT JONES, CFA

Chairman, Arwen Advisors and Chairman and CIO, System Two Advisors

TERENCE LIM, PhD, CFA

CEO, Arwen Advisors

Abstract: Equity portfolio management has evolved considerably since the 1950s. Portfolio theories and asset pricing models, in conjunction with new data sources and powerful computers, have revolutionized the way investors select stocks and create portfolios. Consequently, what was once mostly an art is increasingly becoming a science: Loose rules of thumb are being replaced by rigorous research and complex implementation. While greatly expanding the frontiers of finance, these advances have not necessarily made it any easier for portfolio managers to outperform the market. The two approaches to equity portfolio management are the traditional approach and the quantitative approach. Despite the contrasting of these two approaches by their advocates, they actually share many traits such as applying economic reasoning to identify a small set of key drivers of equity values, using observable data to quantify these key drivers, using expert judgment to develop ways to map these key drivers into the final stock-selection decision, and evaluating their performance over time. The difference in the two approaches is how they perform these tasks.

Equity portfolio management has evolved considerably since Benjamin Graham and David Dodd published their classic text on security analysis in 1934 (Graham and Dodd, 1934). For one, the types of stocks available for investment have shifted dramatically, from companies with mostly physical assets (such as railroads and utilities) to companies with mostly intangible assets (such as technology stocks and pharma-

ceuticals). Moreover, theories such as the modern portfolio theory and the capital asset pricing model, in conjunction with new data sources and powerful computers, have revolutionized the way investors select stocks and create portfolios. Consequently, what was once mostly an art is increasingly becoming a science: Loose rules of thumb are being replaced by rigorous research and complex implementation.

Of course, these new advances, while greatly expanding the frontiers of finance, have not necessarily made it any easier for portfolio managers to beat the market. In fact, the increasing sophistication of the average investor has probably made it more difficult to find—and exploit—pricing errors. Several studies show that a majority of professional money managers have been unable to beat the market (see, for example, Malkiel, 1995). There are no sure bets, and mispricings, when they occur, are rarely both large and long lasting. Successful managers must therefore constantly work to improve their existing strategies and to develop new ones. Understanding fully the equity management process is essential to accomplishing this challenging task.

These new advances, unfortunately, have also allowed some market participants to stray from a sound investment approach. It is now easier than ever for portfolio managers to use biased, unfamiliar, or incorrect data in a flawed strategy, one developed from untested conjecture or haphazard trial and error. Investors, too, must be careful not to let the abundance of data and high-tech techniques distract them when allocating assets and selecting managers. In particular, investors should not allow popular but narrow rankings of short-term performance obscure important differences in portfolio managers' style exposure or investment process. To avoid these pitfalls, it helps to have a solid grasp of the constantly advancing science of equity investing.

This entry provides an overview of equity portfolio management aimed at current and potential investors, analysts, investment consultants, and portfolio managers. We begin with a discussion of the two major approaches to equity portfolio management: the *traditional approach* and the *quantitative approach*. The remaining sections of the entry are organized around four major steps in the investment process: (1) forecasting the unknown quantities needed to manage equity portfolios—returns, risks, and transaction costs; (2) constructing portfo-

lios that maximize expected risk-adjusted return net of transaction costs; (3) trading stocks efficiently; and (4) evaluating results and updating the process.

These four steps should be closely integrated: The return, risk, and transaction cost forecasts, the approach used to construct portfolios, the way stocks are traded, and performance evaluation should all be consistent with one another. A process that produces highly variable, fast-moving return forecasts, for example, should be matched with short-term risk forecasts, relatively high transaction costs, frequent rebalancing, aggressive trading, and short-horizon performance evaluation. In contrast, stable, slower-moving return forecasts can be combined with longer term risk forecasts, lower expected transaction costs, less frequent rebalancing, more patient trading, and longer-term evaluation. Mixing and matching incompatible approaches to each part of the investment process can greatly reduce a manager's ability to reap the full rewards of an investment strategy.

A well-structured investment process should also be supported by sound economic logic, diverse information sources, and careful empirical analysis that together produce reliable forecasts and effective implementation. And, of course, a successful investment process should be easy to explain; marketing professionals, consultants, and investors all need to understand a manager's process before they will invest in it.

TRADITIONAL AND QUANTITATIVE APPROACHES TO EQUITY PORTFOLIO MANAGEMENT

At one level, there are as many ways to manage portfolios as there are portfolio managers. After all, developing a unique and innovative investment process is one of the ways managers distinguish themselves from their peers. Nonetheless, at a more general level, there are

two basic approaches used by most managers: The traditional approach and the quantitative approach. Although these two approaches are often sharply contrasted by their proponents, they actually share many traits. Both apply economic reasoning to identify a small set of key drivers of equity values; both use observable data to help measure these key drivers; both use expert judgment to develop ways to map these key drivers into the final stock-selection decision; and both evaluate their performance over time. What differs most between traditional and quantitative managers is how they perform these steps.

Traditional managers conduct stock-specific analysis to develop a subjective assessment of each stock's unique attractiveness. Traditional managers talk with senior management, closely study financial statements and other corporate disclosures, conduct detailed, stock-specific competitive analysis, and usually build spreadsheet models of a company's financial statements that provide an explicit link between various forecasts of financial metrics and stock prices. The traditional approach involves detailed analysis of a company and is often well equipped to cope with data errors or structural changes at a company (e.g., restructurings or acquisitions). However, because the traditional approach relies heavily on the judgment of analysts, it is subject to potentially severe subjective biases such as selective perception, hindsight bias, stereotyping, and overconfidence that can reduce forecast quality. (For a discussion of the systematic errors in judgment and probability assessment that people frequently make, see Kahneman, Slovic, and Tversky, 1982.) Moreover, the traditional approach is costly to apply, which makes it impracticable for a large investment universe comprising many small stocks. The high cost and subjective nature also make it difficult to evaluate, because it is hard to create the history necessary for testing. Testing an investment process is important because it helps to distinguish factors that are reflected in stock prices from those that are not. Only

factors that are not yet impounded in stock prices can be used to identify profitable trading opportunities. Failure to distinguish between these two types of factors can lead to the familiar "good company, bad stock" problem in which even a great company can be a bad investment if the price paid for the stock is too high.

Quantitative managers use statistical models to map a parsimonious set of measurable factors into objective forecasts of each stock's return, risk, and cost of trading. The quantitative approach formalizes the relation between the key factors and forecasts, which makes the approach transparent and largely free of subjective biases. Quantitative analysis can also be highly cost effective. Although the fixed costs of building a robust quantitative model are high, the marginal costs of applying the model, or extending it to a broader investment universe, are low. Consequently, quantitative portfolio managers can choose from a large universe of stocks, including many small and otherwise neglected stocks that have attractive fundamentals. Finally, because the quantitative approach is model-based, it can be tested historically on a wide cross-section of stocks over diverse economic environments. While quantitative analysis can suffer from specification errors and overfitting, analysts can mitigate these errors by following a well-structured and disciplined research process.

On the negative side, quantitative models can be misleading when there are bad data or significant structural changes at a company (that is, "garbage in, garbage out"). For this reason, most quantitative managers like to spread their bets across many names so that the success of any one position will not make or break the strategy. Traditional managers, conversely, prefer to take fewer, larger bets given their detailed hands-on knowledge of the company and the high cost of analysis.

A summary of the major advantages of each approach to equity portfolio management is presented in Table 1. (Dawes, Faust, and Meehl

Table 1 Major Advantages of the Traditional and Quantitative Approaches to Equity Portfolio Management

Traditional approach	
Depth	Although they have views on fewer companies, traditional managers tend to have more in-depth knowledge of the companies they cover. Unlike a computerized model, they should know when data are misleading or unrepresentative.
Regime shifts	Traditional managers may be better equipped to handle regime shifts and recognize situations where past relationships might not be expected to continue (e.g., where back-tests may be unreliable).
Signal identification	Based on their greater in-depth knowledge, traditional managers can better understand the unique data sources and factors that are important for stocks in different countries or industries.
Qualitative factors	Many important factors that may affect an investment decision are not available in any database and are hard to evaluate quantitatively. Examples might include management and their vision for the company; the value of patents, brands, and other intangible assets; product quality; or the impact of new technology.
Quantitative approach	
Universe	Because a computerized model can quickly evaluate thousands of securities and can update those evaluations daily, it can uncover more opportunities. Further, by spreading their risk across many small bets, quantitative managers can add value with only slightly favorable odds.
Discipline	While individuals often base decisions on only the most salient or distinctive factors, a computerized model will simultaneously evaluate all specified factors before reaching a conclusion.
Verification	Before using any signal to evaluate stocks, quantitative managers will normally backtest its historical efficacy and robustness. This provides a framework for weighting the various signals.
Risk management	By its nature, the quantitative approach builds in the notion of statistical risk and can do a better job of controlling unintended risks in the portfolio.
Lower fees	The economies of scale inherent in a quantitative process usually allow quantitative managers to charge lower fees.

[1989] provide an excellent comparison of clinical (traditional) and actuarial (quantitative) decision analysis.) Our focus in the rest of this entry is the process of quantitative equity portfolio management.

FORECASTING STOCK RETURNS, RISKS, AND TRANSACTION COSTS

Developing good forecasts is the first and perhaps most critical step in the investment process. Without good forecasts, the difficult task of forming superior portfolios becomes nearly

impossible. In this section we discuss how to use a quantitative approach to generate *forecasts of stock returns, risks, and transaction costs*. These forecasts are then used in the portfolio construction step described in the next section.

It should be noted that some portfolio managers do not develop explicit forecasts of returns, risks, and transaction costs. Instead, they map a variety of individual stock characteristics directly into portfolio holdings. However, there are limitations with this abbreviated approach. Because the returns and risks corresponding to the various characteristics are not clearly identified, it is difficult to ensure the weights placed on the characteristics

are appropriate. Further, measuring risk at the portfolio level is awkward without reliable estimates of the risks of each stock, especially the correlations between stocks. Similarly, controlling turnover is hard when returns and transaction costs are not expressed in consistent units. And, of course, it is difficult to explain a process that occurs in one magical step.

Forecasting Returns

The process of building a quantitative return-forecasting model can be divided into four closely linked steps: (1) identifying a set of potential return forecasting variables, or signals; (2) testing the effectiveness of each signal, by itself and together with other signals; (3) determining the appropriate weight for each signal in the model; and (4) blending the model's views with market equilibrium to arrive at reasonable forecasts for expected returns.

Identifying a list of potential *signals* might seem like an overwhelming task; the candidate pool can seem almost endless. To narrow the list, it is important to start with fundamental relationships and sound economics. Reports published by Wall Street analysts and books about financial statement analysis are both good sources for ideas. Another valuable resource is academic research in finance and accounting. Academics have the incentive and expertise to identify and carefully analyze new and innovative information sources. Academics have studied a large number of stock price anomalies, and Table 2 lists several that have been adopted by investment managers. (For evidence on the performance of several well-known anomalies, see Fama and French [2008].)

For portfolio managers intent on building a successful investment strategy, it is not enough to simply take the best ideas identified by others and add them to the return-forecasting model. Instead, each potential signal must be thoroughly tested to ensure it works in the context of the manager's strategy across many stocks and during a variety of economic envi-

Table 2 Selected Stock Price Anomalies Used in Quantitative Models

<i>Growth/Value:</i> Value stocks (high B/P, E/P, CF/P) outperform growth stocks (low B/P, E/P, CF/P).
<i>Post-earnings-announcement drift:</i> Stocks that announce earnings that beat expectations outperform stocks that miss expectations.
<i>Short-term price reversal:</i> One-month losers outperform one-month winners.
<i>Intermediate-term price momentum:</i> Six-months to one-year winners outperform losers.
<i>Earnings quality:</i> Stocks with cash earnings outperform stocks with non-cash earnings.
<i>Stock repurchases:</i> Companies that repurchase shares outperform companies that issue shares.
<i>Analyst earnings estimates and stock recommendations:</i> Changes in analyst stock recommendations and earnings estimates predict subsequent stock returns.

ronments. The real challenge is winnowing the list of potential signals to a parsimonious set of reliable forecasting variables. When selecting a set of signals, it is a good idea to include a variety of variables to capture distinct investment themes, including valuation, momentum, and earnings quality. By diversifying over information sources and variables, there is a good chance that if one signal fails to add value another will be there to carry the load.

When evaluating a signal, it is important to make sure the underlying data used to compute the signal are available and largely error free. Checking selected observations by hand and screening for outliers or other influential observations is a useful way to identify data problems. It is also sometimes necessary to transform a signal—for instance, by subtracting the industry mean or taking the natural logarithm—to improve the “shape” of the distribution. To evaluate a signal properly, both univariate and multivariate analysis is important. Univariate analysis provides evidence on the signal's predictive ability when the signal is used alone, whereas multivariate analysis provides evidence on the signal's incremental predictive ability above and beyond other variables considered. For both univariate and

multivariate analysis, it is wise to examine the returns to a variety of portfolios formed on the basis of the signal. Sorting stocks into quintiles or deciles is popular, as is regression analysis, where the coefficients represent the return to a portfolio with unit exposure to the signal. These portfolios can be equal weighted, cap weighted, or even risk weighted depending on the model's ultimate purpose. Finally, the return forecasting model should be tested using a realistic simulation that controls the target level of risk, takes account of transaction costs, and imposes appropriate constraints (e.g., the nonnegativity constraint for long-only portfolios). In our experience, many promising return-forecasting signals fail to add value in realistic back-tests—either because they involve excessive trading; work only for small, illiquid stocks; or contain information that is already captured by other components of the model.

The third step in building a return forecasting model is determining each signal's weight. When computing expected returns, more weight should be put on signals that, over time, have been more stable; generated higher and more consistent returns; and provided superior diversification benefits. Maintaining exposures to signals that change slowly requires less trading, and hence lower costs, than is the case for signals that change rapidly. Other things being equal, a stable signal (such as the ratio of book-to-market equity) should get more weight than a less stable signal (such as one-month price reversal). High, consistent returns are essential to a profitable, low-risk investment strategy; hence, signals that generate high returns with little risk should get more weight than signals that produce lower returns with higher risk. Finally, signals with more diversified payoffs should get more weight because they can hedge overall performance when other signals in the model perform poorly.

The last step in forecasting returns is to make sure the forecasts are reasonable and internally consistent by comparing them with equilibrium views. Return forecasts that ignore equilibrium

expectations can create problems in the portfolio construction step. Seemingly reasonable return forecasts can cause an optimizer to maximize errors rather than expected returns, producing extreme, unbalanced portfolios. The problem is caused by return forecasts that are inconsistent with the assumed correlations across stocks. If two stocks (or subportfolios) are highly correlated, then the equilibrium expectation is that their returns should be similar; otherwise, the optimizer will treat the pair of stocks as a (near) arbitrage opportunity by going extremely long the high-return stock and extremely short the low-return stock. However, with hundreds of stocks, it is not always obvious whether certain stocks, or combinations of stocks, are highly correlated and therefore ought to have similar return forecasts. The Black-Litterman model was specifically designed to alleviate this problem. It blends a model's raw return forecasts with *equilibrium expected returns*—which are the returns that would make the benchmark optimal for a given risk model—to produce internally consistent return forecasts that reflect the manager's (or model's) views yet are consistent with the risk model. (For a discussion of how to use the Black-Litterman model to incorporate equilibrium views into a return-forecasting model, see Litterman [2003].)

Forecasting Risks

In a portfolio context, the risk of a single stock is a function of the variance of its returns, as well as the covariances between its returns and the returns of other stocks in the portfolio. The variance-covariance matrix of stock returns, or risk model, is used to measure the risk of a portfolio. For equity portfolio management, investors rarely estimate the full variance-covariance matrix directly because the number of individual elements is too large, and for a well-behaved (that is, non-singular) matrix, the number of observations used to estimate the matrix must significantly

exceed the number of stocks in the matrix. To see this, suppose that there are N stocks. Then the variance-covariance matrix has $N(N + 1)/2$ elements, consisting of N variances and $N(N - 1)/2$ covariances. For an S&P 500 portfolio, for instance, there are $500 \times (500 + 1)/2 = 125,250$ unknown parameters to estimate, 500 variances and 124,750 covariances. For this reason, most equity portfolio managers use a *factor risk model* in which individual variances and covariances are expressed as a function of a small set of stock characteristics—such as industry membership, size, and leverage. This greatly reduces the number of unknown risk parameters that the manager needs to estimate.

When developing an equity factor risk model, it is a good idea to include all of the variables used to forecast returns among the (potentially larger) set of variables used to forecast risks. This way, the risk model “sees” all of the potential risks in an investment strategy, both those managers are willing to accept and those they would like to avoid. Further, a mismatch between the variables in the return and risk models can produce less efficient portfolios in the optimizer. For instance, suppose a return model comprises two factors, each with 50% weight: the book-to-price ratio (B/P) and return on equity (ROE). Suppose the risk model, on the other hand, has only one factor: B/P. When forming a portfolio, the optimizer will manage risk only for the factors in the risk model—that is, B/P but not ROE. This inconsistency between the return and risk models can lead to portfolios with extreme positions and higher-than-expected risk. The portfolio will not reflect the original 50-50 weights on the two return factors because the optimizer will dampen the exposure to B/P, but not to ROE. In addition, the risk model’s estimate of tracking error will be too low because it will not capture any risk from the portfolio’s exposure to ROE. The most effective way to avoid these two problems is to make sure all of the factors in the return model are also included in the risk model (although the converse does not need to be true—that

is, there can be risk factors without expected returns).

A final issue to consider when developing or selecting a risk model is the frequency of data used in the estimation process. Many popular risk models use monthly returns, whereas some portfolio managers have developed proprietary risk models that use daily returns. Clearly, when estimating variances and covariances, the more observations, the better. High-frequency data produce more observations and hence more precise and reliable estimates. Further, by giving more weight to recent observations, estimates can be more responsive to changing economic conditions. As a result, risk models that use high-frequency returns should provide more accurate risk estimates. (For a detailed discussion of factor risk models, see Chapter 20 of Litterman [2003]).

Forecasting Transaction Costs

Although often overlooked, accurate trade-cost estimates are critical to the equity portfolio management process. After all, what really matters is not the gross return a portfolio might receive, but rather the actual return a portfolio does receive after deducting all relevant costs, including transaction costs. Ignoring transaction costs when forming portfolios can lead to poor performance because implementation costs can reduce, or even eliminate, the advantages achieved through superior stock selection. Conversely, taking account of transaction costs can help produce portfolios with gross returns that exceed the costs of trading.

Accurate trading-cost forecasts are also important after portfolio formation, when monitoring the realized costs of trading. A good transaction-cost model can provide a benchmark for what realized costs “should be,” and hence whether actual execution costs are reasonable. Detailed trade-cost monitoring can help traders and brokers achieve best execution by driving improvements in trading methods—such as more patient trading,

or the selective use of alternative trading mechanisms.

Transaction costs have two components: (1) explicit costs, such as commissions and fees; and (2) implicit costs, or market impact. Commissions and fees tend to be relatively small, and the cost per share does not depend on the number of shares traded. In contrast, market impact costs can be substantial. They reflect the costs of consuming liquidity from the market, costs that increase on a per-share basis with the total number of shares traded.

Market impact costs arise because suppliers of liquidity incur risk. One component of these costs is inventory risk. The liquidity supplier has a risk/return trade-off, and will demand a price concession to compensate for this inventory risk. The larger the trade size and the more illiquid or volatile the stock, the larger are inventory risk and market impact costs. Another consideration is adverse selection risk. Liquidity suppliers are willing to provide a better price to uninformed than informed traders, but since there is no reliable way to distinguish between these two types of traders, the market maker sets an average price, with expected gains from trading with uninformed traders compensating for losses incurred from trading with informed traders. Market impact costs tend to be higher for low-price and small-cap stocks for which greater adverse selection risk and informational asymmetry tend to be more severe.

Forecasting price impact is difficult. Because researchers only observe prices for completed trades, they cannot determine what a stock's price would have been without these trades. It is therefore impossible to know for sure how much prices moved as a result of the trade. Price impact costs, then, are statistical estimates that are more accurate for larger data samples.

One approach to estimating trade costs is to directly examine the complete record of market prices, tick by tick (see, for example, Breen, Hodrick, and Korajczyk [2002]). These data are noisy due to discrete prices, non-synchronous reporting of trades and quotes, and input er-

rors. Also, the record does not show orders placed, just those that eventually got executed (which may have been split up from the original, larger order). Research by Lee and Radhakrishna (2000) suggests empirical analysis should be done using aggregated samples of trades rather than individual trades at the tick-by-tick level.

Another approach is for portfolio managers to estimate a proprietary transaction cost model using their own trades and, if available, those of comparable managers. If generating a sufficient sample is feasible, this approach is ideal because the resulting model matches the stock characteristics, investment philosophy, and trading strategy of the individual portfolio manager. There is a large academic literature on measuring transaction costs. Further, models built from actual trading records provide a complementary source of information on market impact costs. (For empirical evidence on how transaction costs can vary across trade characteristics and how to predict transaction costs, see Chapter 23 of Litterman [2003].)

CONSTRUCTING PORTFOLIOS

In this section we discuss how to construct portfolios based on the forecasts described in the last section. In particular, we compare ad hoc, rule-based approaches to portfolio optimization. The first step in portfolio construction, however, is to specify the investment goals. While having good forecasts (as described in the previous section) is obviously important, the investor's goals define the portfolio management problem. These goals are usually specified by three major parameters: the benchmark, the risk/return target, and specific restrictions such as the maximum holdings in any single name, industry, or sector.

The benchmark represents the starting point for any active portfolio; it is the client's neutral position—a low-cost alternative to active

management in that asset class. For example, investors interested in holding large-cap U.S. stocks might select the S&P 500 or Russell 1000 as their benchmark, while investors interested in holding small-cap stocks might choose the Russell 2000 or the S&P 600. Investors interested in a portfolio of non-U.S. stocks could pick the FTSE 350 (United Kingdom), TOPIX (Japan), or MSCI EAFE (World minus North America) indexes. There are a large number of published benchmarks available, or an investor might develop a customized benchmark to represent the neutral position. In all cases, however, the benchmark should be a reasonably low-cost, investable alternative to active management.

Although some investors are content to merely match the returns on their benchmarks, most investors allocate at least some of their assets to active managers. The allocation of risk is done via *risk budgeting*. In equity portfolio management, active management means overweighting attractive stocks and underweighting unattractive stocks relative to their weights in the benchmark. (The difference between a stock's weight in the portfolio and its weight in the benchmark is called its active weight, where a positive active weight corresponds to an overweight position and a negative active weight corresponds to an underweight position.) Of course, there is always a chance that these active weighting decisions will cause the portfolio to underperform the benchmark, but one of the basic dictums of modern finance is that to earn higher returns, investors must accept higher risk—which is true of active returns as well as total returns.

A portfolio's *tracking error* measures its risk relative to a benchmark. Tracking error equals the time-series standard deviation of a portfolio's *active return* (which is the difference between the portfolio's return and that of the benchmark). A portfolio's *information ratio* equals its average active return divided by its tracking error. As a measure of return per unit of risk, the information ratio provides a conve-

nient way to compare strategies with different active risk levels.

An *efficient portfolio* is one with the highest expected return for a target level of risk—that is, it has the highest information ratio possible given the risk budget. In the absence of constraints, an efficient portfolio is one in which each stock's marginal contribution to expected return is proportional to its marginal contribution to risk. That is, there are no unintended risks, and all risks are compensated with additional expected returns. How can a portfolio manager construct such an efficient portfolio? Below we compare two approaches: (1) a rule-based system; and (2) portfolio optimization.

Building an efficient portfolio is a complex problem. To help simplify this complicated task, many portfolio managers use ad hoc, rule-based methods that partially control exposures to a small number of risk factors. For example, one common approach—called stratified sampling—ranks stocks within buckets formed on the basis of a few key risk factors, such as sector and size. The manager then invests more heavily in the highest-ranked stocks within each bucket, while keeping the portfolio's total weight in each bucket close to that of the benchmark. The resulting portfolio is close to neutral with respect to the identified risk factors (that is, sector and size) while overweighting attractive stocks and underweighting unattractive stocks.

Although stratified sampling may seem sensible, it is not very efficient. Numerous unintended risks can creep into the portfolio, such as an overweight in high-beta stocks, growth stocks, or stocks in certain subsectors. Nor does it allow the manager to explicitly consider trading costs or investment objectives in the portfolio construction problem. Portfolio optimization provides a much better method for balancing expected returns against different sources of risk, trade costs, and investor constraints. An optimizer uses computer algorithms to find the set of weights (or holdings) that maximize the portfolio's expected return

(net of trade costs) for a given level of risk. It minimizes uncompensated sources of risk, including sector and style biases. Fortunately, despite the complex math, optimizers require only the various forecasts we've already described and developed in the prior section.

Chapter 23 of Litterman (2003) demonstrates the benefits of optimization, comparing two portfolios: one constructed using stratified sampling and the other constructed using an optimizer. The *optimized portfolio* is designed to have the same predicted tracking error as the *rule-based portfolio*. The results show that (1) the optimized portfolio is more efficient in terms of its expected alpha and information ratio for the same level of risk, (2) risk is spread more broadly for the optimized portfolio compared to the rule-based portfolio, (3) more of the risk budget in the optimized portfolio is due to the factors that are expected to generate positive excess returns, and (4) the forecast beta for the optimized portfolio is closer to 1.0, as unintended sources of risk (such as the market timing) are minimized.

Another benefit of optimizers is that they can efficiently account for transaction costs, constraints, selected restrictions, and other account guidelines, making it much easier to create customized client portfolios. Of course, when using an optimizer to construct efficient portfolios, reliable inputs are essential. Data errors that add noise to the return, risk, and transaction cost forecasts can lead to portfolios in which these forecast errors are maximized. Instead of picking stocks with the highest actual expected returns, or the lowest actual risks or transaction costs, the optimizer takes the biggest positions in the stocks with the largest errors, namely, the stocks with the greatest overestimates of expected returns or the greatest underestimates of risks or transaction costs. A robust investment process will screen major data sources for outliers that can severely corrupt one's forecasts. Further, as described in the previous section, return forecasts should be adjusted for equilibrium views using the

Black-Litterman model to produce final return forecasts that are more consistent with risk estimates, and with each other. Finally, portfolio managers should impose sensible, but simple, constraints on the optimizer to help guard against the effects of noisy inputs. These constraints could include maximum active weights on individual stocks, industries, or sectors, as well as limitations on the portfolio's active exposure to factors such as size or market beta.

TRADING

Trading is the process of executing the orders derived in the portfolio construction step. To trade a list of stocks efficiently, investors must balance opportunity costs and execution price risk against market impact costs. Trading each stock quickly minimizes lost alpha and price uncertainty due to delay, but impatient trading incurs maximum market impact. However, trading more patiently over a longer period reduces market impact but incurs larger opportunity costs and short-term execution price risk. Striking the right balance is one of the keys to successful trade execution.

The concept of "striking a balance" suggests optimization. Investors can use a trade optimizer to balance the gains from patient trading (e.g., lower market-impact cost) against the risks (e.g., greater deviation between the execution price and the decision price; potentially higher short-term tracking error). Such an optimizer will tend to suggest aggressive trading for names that are liquid and/or have a large effect on portfolio risk, while suggesting patient trading for illiquid names that have less impact on risk. A trade optimizer can also easily handle most real-world trading constraints, such as the need to balance cash in each of many accounts across the trading period (which may last several days).

A trade optimizer can also easily accommodate the time horizon of a manager's views. That is, if a manager is buying a stock primarily for long-term valuation reasons, and the excess

return is expected to accrue gradually over time, then the optimizer will likely suggest a patient trading strategy (all else being equal). Conversely, if the manager is buying a stock in expectation of a positive earnings surprise tomorrow, the optimizer is likely to suggest an aggressive trading strategy (again, all else being equal). The trade optimizer can also be programmed to consider short-term return regularities, such as the tendency of stocks with dramatic price moves on one day to continue those moves on the next day before reversing the following day (see Heston, Korajczyk, and Sadka, 2010). Although these types of regularities may be too small to cover trading costs, and should not be used to initiate trades, they can be used to help minimize trading costs after an investor has independently decided to trade (see Engle and Ferstenberg, 2007).

To induce traders to follow the desired strategy (that is, that suggested by the trade optimizer), the portfolio manager needs to give the trader an appropriate benchmark, which provides guidance about how aggressively or patiently to trade. Two widely used benchmarks for aggressive trades are the closing price on the previous day and the opening price on the trade date. Because the values of these two benchmarks are measured prior to any trading, a patient strategy that delays trading heightens execution price risk by increasing the possibility of deviating significantly from the benchmark. Another popular execution benchmark is the volume-weighted average price (VWAP) for the stock over the desired trading period, which could be a few minutes or hours for an aggressive trade, or one or more days for a patient trade. However, the VWAP benchmark should only be used for trades that are not too large relative to total volume over the period; otherwise, the trader may be able to influence the benchmark against which he or she is evaluated.

Buy-side traders can increasingly make use of algorithmic trading, or computer algorithms that directly access market exchanges, to auto-

matically make certain trading decisions such as the timing, price, quantity, type, and routing of orders. These algorithms may dynamically monitor market conditions across time and trading venues, and reduce market impact by breaking large orders into smaller pieces, employing either limit orders or marketable limit orders, or selecting trading venues to submit orders, while closely tracking trading benchmarks. Algorithmic trading provides buy-side traders more anonymity and greater control over their order flow, but tends to work better for more liquid or patient trades.

Principal package trading is another way to lower transaction costs relative to traditional agency methods (see Kavajecz and Keim, 2005). Principal trades may be crossed with the principal's existing inventory positions, or allow the portfolio manager to benefit from the longer trading horizon and superior trading ability of certain intermediaries.

EVALUATING RESULTS AND UPDATING THE PROCESS

Once an investment process is up and running, it needs to be constantly reassessed and, if necessary, refined. The first step is to compare actual results to expectations; if realizations differ enough from expectations, process refinements may be necessary. Thus, managers need systems to monitor realized performance, risk, and trading costs and compare them to prior expectations.

A good performance monitoring system should be able to determine not only the degree of over- or under-performance, but also the sources of these excess returns. For example, a good performance attribution system might break excess returns down into those due to market timing (having a different beta than the benchmark), industry tilts, style differences, and stock selection. Such systems are available from a variety of third-party vendors. An even better system would allow the manager to

further disaggregate returns to see the effects of each of the proprietary signals used to forecast returns, as well as the effects of constraints and other portfolio requirements. And, of course, any system will be more accurate if it can account for daily trading and changes in portfolio exposures.

Investors should also compare realized risks to expectations. For example, Goldman Sachs has developed the concept of the green, yellow, and red zones to compare realized and targeted levels of risk (see Chapter 17 in Litterman, 2003). Essentially, if realized risk is within a reasonable band around the target (that is, the green zone), then one can assume the risk management techniques are working as intended and no action is required. If realized risk is further from the target (the yellow zone), the situation may require closer examination, and if realized risk is far from the target (the red zone), some action is usually called for.

Finally, it is important to monitor trading costs. Are they above or below the costs assumed when making trading decisions? Are they above or below competitors' costs? Are they too high in an absolute sense? If so, managers may need to improve their trade cost estimates, trading process, or both. There are many services that can report realized trade costs, but most are available with a significant lag, and are inflexible with respect to how they measure and report these costs. With in-house systems, however, managers can compare a variety of trade cost estimation techniques and get the feedback in a timely enough fashion to act on the results.

The critical question, of course, is what to do with the results of these monitoring systems: When do variations from expectations warrant refinements to the process? This will depend on the size of the variations and their persistence. For example, a manager probably would not throw out a stock-selection signal after one bad month—no matter how bad—but might want to reconsider after many years of poor performance, taking into consideration the eco-

nomic environment and any external factors that might explain the results. It is also important to compare the underperformance to historical simulations. Have similar periods occurred in the past, and if so, were they followed by improvements? In this case, the underperformance is part of the normal risk in that signal and no changes may be called for. If not, there may have been a structural change that might invalidate the signal going forward—for example, if the signal has become overly popular, it may no longer be a source of mispricing.

Similarly, the portfolio manager needs to consider the source of any differences between expectations and realizations. For example, was underperformance due to faulty signals, portfolio constraints, unintended risk, or random noise? The answer will determine the proper response. If constraints are to blame, they may be lifted—but only if doing so would not violate any investment guidelines or incur excessive risk. Alternatively, if the signals are to blame, the manager must decide if the deviations from expectations are temporary or more enduring. If it is just random noise, no action is necessary. Similarly, any differences between realized and expected risk could be due to poor risk estimates or poor portfolio construction, with the answer determining the response. Finally, excessive trading costs (versus expectations) could reflect poor trading or poor trade cost estimates, again with different implications for action.

In summary, ongoing performance, risk, and trade cost monitoring is an integral part of the equity portfolio management process and should get equal billing with forecasting, portfolio construction, and trading. Monitoring serves as both quality control and a source of new ideas and process improvements. The more sophisticated the monitoring systems, the more useful they are to the process. And although the implications of monitoring involve subtle judgments and careful analysis, better data can lead to better solutions.

KEY POINTS

- Two popular ways to manage equity portfolios are the traditional, or qualitative, approach and the quantitative approach.
- The equity investment process comprises four primary steps: (1) forecasting returns, risks, and transaction costs; (2) constructing portfolios that maximize expected risk-adjusted return net of transaction costs; (3) trading stocks efficiently; and (4) evaluating results and updating the process.
- There are four closely linked steps to building a quantitative equity return-forecasting model: (1) identifying a set of potential return forecasting variables, or signals; (2) testing the effectiveness of each signal, by itself and together with other signals; (3) determining the appropriate weight for each signal in the model; and (4) blending the model's views with market equilibrium to arrive at reasonable forecasts for expected returns.
- Most quantitative equity portfolio managers use a factor risk model in which individual variances and covariances are expressed as a function of a small set of stock characteristics such as industry membership, size, and leverage.
- Transaction costs consist of explicit costs, such as commissions and fees, and implicit costs, or market impact. The per-share cost of commissions and fees does not depend on the number of shares traded, whereas market impact costs increase on a per-share basis with the total number of shares traded.
- Tracking error measures a portfolio's risk relative to a benchmark. Tracking error equals the time-series standard deviation of a portfolio's active return, the difference between the portfolio's return and that of the benchmark.
- Information ratio is a measure of return per unit of risk, a portfolio's average active return divided by its tracking error.
- Two widely used ways to construct an efficient portfolio are stratified sampling, which

is a rule-based system, and portfolio optimization.

- To trade a list of stocks efficiently, investors must balance opportunity costs and execution price risk against market impact costs. Trading each stock quickly minimizes lost alpha and price uncertainty due to delay, but impatient trading incurs maximum market impact. Trading more patiently over a longer period reduces market impact but incurs larger opportunity costs and short-term execution price risk.
- Once an investment process is operational, it should be constantly reassessed and, if necessary, refined. Thus, managers need systems to monitor realized performance, risk, and trading costs and compare them to prior expectations.
- A good performance monitoring system should be able to determine the degree of over- or underperformance as well as the sources of these excess returns, such as market timing, industry tilts, style differences, and stock selection.

Partner, The Intertek Group

Abstract: One of the key tasks in seeking to generate attractive returns is producing realistic and reasonable return expectations and forecasts. In the Markowitz mean-variance framework, an investor's objective is to choose a portfolio of securities that has the largest expected return for a given level of risk (as measured by the portfolio's variance). In the case of common stock, by return (or expected return) of a stock, we mean the change (or expected change) in the stock price over the period, plus any dividends paid, divided by the starting price. Of course, since we do not know the true values of the securities' expected returns and covariances, these must be estimated or forecasted. Equity portfolio managers have used various statistical models for forecasting returns and risk. These models, referred to as predictive return models, make conditional forecasts of expected returns using the current information set. Predictive return models include regressive models, linear autoregressive models, dynamic factor models, and hidden-variable models.

In contrast to forecasting events such as the weather, forecasting stock prices and returns is difficult because the predictions themselves will produce market movements that in turn provoke immediate changes in prices, thereby invalidating the predictions themselves. This leads to the concept of market efficiency: An efficient market is a market where all new information about the future behavior of prices is immediately impounded in the prices themselves and therefore exploits all information.

Actually the debate about the predictability of stock prices and returns has a long history.¹ More than 75 years ago, Cowles (1933) asked the question: "Can stock market forecasters forecast?" Armed with the state-of-the-art econometric tools at the time, Cowles analyzed the recommendations of stock market forecasters and concluded, "It is doubtful." Subsequent academic studies support Cowles's conclusion. However, the history goes further back. In 1900, a French mathematician, Louis Bachelier, in his doctoral dissertation in mathematical statistics

titled *Théorie de la Spéculation* (*The Theory of Speculation*), showed using mathematical techniques why the stock market behaves as it does.² He also provided empirical evidence based on the French capital markets at the turn of the century. He wrote:

Past, present, and even discounted future events are reflected in market price, but often show no apparent relation to price changes. . . . [A]rtificial causes also intervene: the Exchange reacts on itself, and the current fluctuation is a function, not only of the previous fluctuations, but also of the current state. The determination of these fluctuations depends on an infinite number of factors; it is, therefore, impossible to aspire to mathematical predictions of it. . . . [T]he dynamics of the Exchange will never be an exact science. (Bachelier, 1900)

In other words, according to Bachelier, stock price movements are difficult to forecast and even explain after the fact.

Despite this conclusion, the adoption of modeling techniques by asset management firms has greatly increased since the turn of the century. Models to predict expected returns are routinely used at asset management firms. In most cases, it is a question of relatively simple models based on factors or predictor variables. However, more statistical or econometric-oriented models are also being experimented with and adopted by some asset management firms, as well as what are referred to as nonlinear models based on specialized areas of statistics such as neural networks and genetic algorithms.

Historical data are often used for forecasting future returns as well as estimating risk. For example, a portfolio manager might proceed in the following way: Observing weekly or monthly returns, the portfolio manager might use the past five years of historical data to estimate the expected return and the covariances by the sample mean and sample covariances. The portfolio manager would then use these as inputs for mean-variance optimization, along with any ad hoc adjustments to reflect any views about expected returns on future performance. Unfortunately this historical approach

most often leads to counterintuitive, unstable, or merely “wrong” portfolios generated by the mean-variance optimization model. Better forecasts are necessary. Statistical estimates can be very noisy and typically depend on the quality of the data and the particular statistical techniques used to estimate the inputs. In general, it is desirable that an estimator of expected return and risk have the following properties:

- It provides a forward-looking forecast with some predictive power, not just a backward-looking historical summary of past performance.
- The estimate can be produced at a reasonable computational cost.
- The technique used does not amplify errors already present in the inputs used in the process of estimation.
- The forecast should be intuitive, that is, the portfolio manager should be able to explain and justify them in a comprehensible manner.

In this entry, we look at the issue of whether forecasting stock returns can be done so as to generate trading profits and excess returns. Because the issue about predictability of stock returns or prices requires an understanding of statistical concepts, we will provide a brief description of the relevant concepts in probability theory and statistics. We then discuss the different types of predictive return models that are used by portfolio managers.

THE CONCEPT OF PREDICTABILITY

To predict (or forecast) involves forming an expectation of a future event or future events. Since ancient times it has been understood that the notion of predicting the future is subject to potential inconsistencies. Consider what might happen if one receives a highly reliable prediction that tomorrow one will have a car accident driving to work. This might alter one’s behavior such that a decision is made not to go to

work. Hence, one's behavior will be influenced by the prediction, thus potentially invalidating the prediction. It is because of inconsistencies of this type that two economists in the mid 1960s, Paul Samuelson and Eugene Fama, arrived at the apparently paradoxical conclusion that "properly anticipated prices fluctuate randomly."³

The concept of forecastability rests on how one can forecast the future given the current state of knowledge. In probability theory, the state of knowledge on a given date is referred to as the *information set* known at that date. Forecasting is the relationship between the information set today and future events. By altering the information set, the forecast changes. However, the relationship between the information set and the future is fixed and immutable. Academicians and market practitioners adopt in finance theories this concept of forecastability. Prices or returns are said to be forecastable if the knowledge of the past influences our forecast of the future. For example, if the future returns of a firm's stock depend on the value of key financial ratios, then those returns are predictable. If the future returns of that stock do not depend on any variable known today, then returns are unpredictable.

As explained in the introduction to this entry, the merits of stock return forecasting is an ongoing debate. There are two beliefs that seem to be held in the investment community. First, predictable processes allow investors to earn excess returns. Second, unpredictable processes do not allow investors to earn excess returns. Neither belief is necessarily true. Understanding why will shed some light on the crucial issues in the debate regarding return modeling. The reasons can be summed up as follows. First, predictable processes do not necessarily produce excess returns if they are associated with unfavorable risk. Second, unpredictable expectations can be profitable if the expected value is favorable.

Because most of our knowledge is uncertain, our forecasts are also uncertain. Probability the-

ory provides the conceptual tools to represent and measure the level of uncertainty.⁴ Probability theory assigns a number—referred to as the "probability"—to every possible event. This number, the probability, might be interpreted in one of two ways. The first is that a probability is the "intensity of belief" that an event will occur, where a probability of 1 means certainty.⁵ The second interpretation is the one normally used in statistics: Probability is the percentage of times (i.e., frequency) that a particular event is observed in a large number of observations (or trials).⁶ This interpretation of probability is the frequentist interpretation, also referred to as the relative frequency concept of probability. Although it is this interpretation that is used in finance and the one adopted in this book, there are attempts to apply the subjective interpretation to financial decision making using an approach called the Bayesian approach.⁷

With this background, let's consider again the returns of some stock. Suppose that returns are unpredictable in the sense that future returns do not depend on the current information set. This does not mean that future returns are completely uncertain in the same sense in which the outcome of throwing a die is uncertain. Clearly, we cannot believe that every possible return on the stock is equally likely: There are upper and lower bounds for real returns in an economy. More important, if we collect a series of historical returns for a stock, a distribution of returns would be observed.

It is therefore reasonable to assume that our uncertainty is embodied in a probability distribution of returns. The absence of *predictability* means that the distribution of future returns does not change as a function of the current information set. More specifically, the distribution of future returns does not change as a function of the present and past values of prices and returns. This entails that the distribution of returns does not change with time. We can therefore state that (1) a price or return process is predictable if its probability distributions depend on the current information set, and (2) a price or

return process is unpredictable if its probability distributions are time-invariant.

Given the concept of predictability as we have just defined it, we can now discuss why prices and returns are difficult (or perhaps impossible) to predict. The key is that any prediction that might lead to an opportunity to generate a trading profit or an excess return tends to make that opportunity disappear. For example, suppose that the price of a stock is predicted to increase significantly in the next five trading days. A large price increase is a source of trading profit or excess return. As a consequence, if that prediction is widely shared by the investment community, investors will rush to purchase that stock. But the demand thus induced will make the stock's price rise immediately, thus eliminating the source of trading profit or excess return and invalidating the forecast.

Suppose that the predictions of stock returns were certain rather than uncertain. By a certain prediction it is meant a prediction that leaves no doubt about what will happen. For example, U.S. Treasury zero-coupon securities if held to maturity offer a known or certain prediction of returns because the maturity value is guaranteed by the full faith and credit of the U.S. government. Any forecast that leaves open the possibility that market forces will alter the forecast cannot be considered a certain forecast. If stock return predictions are certain, then simple arbitrage arguments would dictate that all stocks should have the same return. In fact, if stock returns could be predicted with certainty and if there were different returns, then investors would choose only those stocks with the highest returns.

Stock return forecasts are not certain; as we have seen, uncertain predictions are embodied in probability distributions. Suppose that we have a joint probability distribution of the returns of the universe of investable stocks. Investors will decide the rebalancing of their portfolios depending on their probabilistic predictions and their risk-return preferences. The problem we are discussing here is whether gen-

eral considerations of market efficiency are able to determine the mathematical form of price or return processes. In particular, we are interested in understanding if stock prices or returns are necessarily unpredictable.

The problem discussed in the literature is expressed roughly as follows. Suppose that returns are a series of random variables. These series will be fully characterized by the joint distributions of returns at any given time t and at any given set of different times. Suppose that investors know these distributions and that they select their portfolios according to specific rules that depend on these distributions. Can we determine the form of admissible processes, that is, of admissible distributions?

Ultimately, the objective in solving this problem is to avoid models that allow unreasonable inferences. Historically, three solutions have been proposed:

1. Returns fluctuate randomly around a given mean.
2. Returns are a fair game.
3. Returns are a fair game after adjusting for risk.

In statistical terminology, returns fluctuating randomly around a given mean refers to returns following *multivariate random walks*. A fair game means that returns are *martingales*. These concepts and their differences will be explained below. The first two proposed solutions are incorrect; the third is too general to be useful for asset management. Before we discuss the above models of prices, we digress to briefly explain some statistical concepts.

Statistical Concepts of Predictability and Unpredictability

Because we have stressed how we must rely on probability to understand the concepts of predictability and unpredictability, we will first explain the concepts of conditional probability, conditional expectation, independent and identically distributed random variables, strict

white noise, martingale difference sequence, and white noise. In addition, we have to understand the concept of an error term and an innovation.

Conditional probability and conditional expectation are fundamental in the probabilistic description of financial markets. A conditional probability of some random variable X is the probability for X given a particular value for another random variable Y is known. Similarly, a conditional probability distribution can be determined. For the conditional probability distribution, an expected value can be computed and is referred to as a conditional expected value or conditional mean or, more commonly, a conditional expectation.

The statistical concept independent and identically distributed variables (denoted by IID variables) means two conditions about probability distributions for random variables. First consider "independent." This means if we have a time series for some random variable, then at each time the random variable has a probability distribution. By independently distributed, it is meant that the probability distributions remain the same regardless of the history of past values for the random variable. "Identically" distributed means that all returns have the same distribution in every time period. These two conditions entail that, over time, the mean and the variance do not change from period to period. In the parlance of the statistician, we have a stationary time-series process.

A strict white noise is a sequence of IID variables that have a mean equal to zero and a finite variance. Hence, a strict white noise is unpredictable in the sense that the conditional probability distribution of the random variables is fixed and independent from the past. Because a strict white noise is unpredictable, expectations and higher moments are unpredictable. Moments are measures to summarize the probability distribution. The first four moments are expected value or mean (location), variance (dispersion), skewness

(asymmetry), and kurtosis (concentration in the tails). The higher moments of a probability distribution are those beyond the mean and variance, that is skewness and kurtosis.

A martingale difference sequence is a sequence of random variables that have a mean of zero that are uncorrelated such that their conditional expectations given the past values of the series is always zero. Because expectations and conditional expectations are both zero, in a martingale difference sequence, expectations are unpredictable. However, if higher moments exist, they might be predictable.

A white noise is a sequence of uncorrelated random variables with a mean of zero and a finite variance. Since the random variables are uncorrelated, in a white noise expectations are linearly unpredictable. Higher moments, if they exist, might be predictable. The key here is that they are unpredictable using a linear model. However, they may be predicted as nonlinear functions of past values. It is for this reason that certain statistical techniques that involve nonlinear functions such as neural networks have been used by some quantitative asset management firms to try to predict expectations.

Random Walks and Martingales

In the special case where the random variables are normally distributed, it can be proven that strict white noise, martingale difference sequence, and white noise coincide. In fact, two uncorrelated, normally distributed random variables are also independent.

We can now define what is meant by an arithmetic random walk, a martingale, and a strict arithmetic random walk that are used to describe the stochastic process for returns and prices as follows:

- An arithmetic random walk is the sum of white-noise terms. The mean of an arithmetic random walk is linearly unpredictable but might be predictable with nonlinear predictors. Higher moments might be predictable.

- A *martingale* is the sum of martingale difference sequence terms. The mean of a martingale is unpredictable (linearly and nonlinearly); that is, the expectation of a martingale coincides with its present value. Higher moments might be predictable.
- A strict random walk is the sum of strict white-noise terms. A strict random walk is unpredictable: Its mean, variance, and higher moments are all unpredictable.

Error Terms and Innovations

Any statistical process can be broken down into a predictable and an unpredictable component. The first component is that which can be predicted from the past values of the process. The second component is that which cannot be predicted. The component that cannot be predicted is called the innovation process. Innovation is not specifically related to a model, it is a characteristic of the process. Innovations are therefore unpredictable processes.

Now consider a model that is supposed to explain empirical data such as predicting future returns or prices. For a given observation, the difference between the value predicted by the model and the observation is called the residual. In econometrics, the residual is referred to as an error term or, simply, error of the model. It is not necessarily true that errors are innovations; that is, it is not necessarily true that errors are unpredictable. If errors are innovations, then the model offers the best possible explanation of data. If not, errors contain residual forecastability. The previous discussion is relevant because it makes a difference if errors are strict white noise, martingale difference sequences, or simply white noise.

More specifically, a random walk whose changes (referred to as increments) are non-normal white noise contains a residual structure not explained by the model both at the level of expectations and higher moments. If data follow a martingale model, then expectations are completely explained by the model but higher moments are not.

The Importance of the Statistical Concepts

We have covered a good number of complex statistical concepts. What's more, many of these statistical concepts are not discussed in basic statistics courses offered in business schools. So, why are these apparently arcane statistical considerations of practical significance to investors? The reason is that the properties of models that are used in attempting to forecast returns and prices depend on the assumptions made about "noise" in the data. For example, a linear model makes linear predictions of expectations and cannot capture nonlinear events such as the clustering of volatility that have been observed in real-world stock markets. It is therefore natural to assume that errors are white noise. In other models attempting to forecast returns and prices, however, different assumptions about noise need to be made; otherwise the properties of the model conflict with the properties of the noise term.

Now, the above considerations have important practical consequences when testing error terms to examine how well the models that will be described later in this entry perform. When testing a model, one has to make sure that the residuals have the properties that we assume they have. Thus, if we use a linear model, say a linear regression, we will have to make sure that residuals from time-series data are white noise; that is, that the residuals are uncorrelated over time. The correlation between the residuals at different times from a model based on time-series data is referred to as autocorrelation. In a linear regression using time-series data, the presence of autocorrelation violates the ordinary least squares assumption when estimating the parameters of the statistical model.⁸ In general, it will suffice to add lags to the set of predictor variables to remove the existence of autocorrelation of the residuals.⁹ However, if we have to check that residuals are martingale difference sequences or strict white noise, we will have to use more powerful tests. In addition, adding lags will not be sufficient to remove undesired properties of residuals. Models

will have to be redesigned. These effects are not marginal: They can have a significant impact on the profitability and performance of investment strategies.

A CLOSER LOOK AT PRICING MODELS

Armed with these concepts from statistics, let's now return to a discussion of pricing models. The first hypothesis on equity price processes that was advanced as a solution to the problem of forecastability was the random walk hypothesis. The strongest formulation assumes that returns are a sequence of IID variables, that is, a strict random walk. This means that, over time, the mean and the variance do not change from period to period. If returns are IID variables, it can be shown that the logarithms of prices follow a random walk and the prices themselves follow what is called a geometric random walk. The IID model is clearly a model without forecastability as the distribution of future returns does not depend on any information set known at the present moment. It does, however, allow stock prices to have a fixed drift.

There is a weaker form of the random walk hypothesis that only requires that returns at any two different times be uncorrelated. According to this weaker definition, returns are a sequence formed by a constant drift plus white noise. If returns are a white noise, however, they are not unpredictable. In fact, a white noise, although uncorrelated at every lag, might be predictable in the sense that its expectation might depend on the present information set.

At one time, it was believed that if one assumes investors make perfect forecasts, then the strict random walk model was the only possible model. However, this conclusion was later demonstrated to be incorrect by LeRoy (1973). He showed that the class of admissible models is actually much broader. That is, the strict random walk model is too restricted to be the

only possible model and proposed the use of the martingale model (i.e., the fair game model) that we explain next.

The idea of a martingale has a long history in gambling. Actually the word "martingale" originally meant a gambling strategy in which the gambler continually doubles his or her bets. In modern statistics, a martingale embodies the idea of a fair game where, at every bet, the gambler has exactly the same probability of winning or losing. In fact, as explained earlier in this entry, the martingale is a process where the expected value of the process at any future date is the actual value of the process. If a price process or a game is represented by a martingale, then the expectation of gains or losses is zero. As from our discussion, a random walk with uncorrelated increments is not necessarily a martingale as its expectations are only linearly unpredictable.

Technically, the martingale model applies to the logarithms of prices. Returns are the differences of the logarithms of prices. The martingale model requires that the expected value of returns is not predictable because it is zero or a fixed constant. However, there can be subtle patterns of forecastability for higher moments of the return distribution. Higher moments, to repeat, are those moments of a probability distribution beyond the expected value (mean) and variance, for example, skewness and kurtosis. In other words, the distribution of returns can depend on the present information set provided that the expected value of the distribution remains constant.

The martingale model does not fully take into consideration risk premiums because it allows higher moments of returns to vary while expected values remain constant. It cannot be a general solution to the problem of what processes are compatible with the assumptions that investors can make perfect probabilistic forecasts.

The definitive answer is due to Harrison and Kreps (1979) and Harrison and Pliska (1981, 1985). They demonstrated that stock prices

must indeed be martingales but after multiplication for a factor that takes into account risk. The conclusion of their work (which involves a very complicated mathematical model), however, is that a broad variety of predictable processes are compatible with the assumption that the market is populated by market agents capable of making perfect forecasts in a probabilistic sense. Predictability is due to the interplay of risk and return.

However, it is precisely due to the market being populated by market agents capable of making perfect forecasts, it is not necessarily true that successful predictions will lead to excess returns. For example, it is generally accepted that predicting volatility is easier than predicting returns. The usual explanation of this fact is that investors and portfolio managers are more interested in returns than in volatility. With the maturing of the quantitative methods employed by asset managers coupled with the increased emphasis placed on risk-return, risk and returns have become equally important. However, this does not entail that both risk and returns have become unpredictable. It is now admitted that it is possible to predict combinations of the two.

PREDICTIVE RETURN MODELS

Equity portfolio managers have used various statistical models for forecasting returns and risk. These models, referred to as *predictive return models*, make conditional forecasts of expected returns using the current information set. That information set could include past prices, company information, and financial market information such as economic growth or the level of interest rates.

Most predictive return models employed in practice are statistical models. More specifically, they use tools from the field of econometrics. We will provide a nontechnical review of econometric-based predictive return models below.

Predictive return models can be classified into four general types:¹⁰

1. *Regressive model*. This model involves the use of regression analysis where the variables used to predict returns (also referred to as predictors or explanatory variables) are the factors that are believed to impact returns.
2. *Linear autoregressive model*. In this model, the variables used to predict returns are the lagged returns (i.e., past returns).
3. *Dynamic factor model*. Models of this type use a mix of prices and returns.
4. *Hidden-variable model*. This type of model seeks to capture regime change.

Although these models use traditional econometric techniques and are the most commonly used in practice, in recent years other models based on the specialized area of machine learning have been proposed. The machine-learning approach in forecasting returns involves finding a model without any theoretical assumptions. This is done through a process of what is referred to as progressive adaptation. Machine-learning approaches, rooted in the fields of statistics and artificial intelligence (AI), include neural networks, decision trees, clustering, genetic algorithms, support vector machines, and text mining.¹¹ We will not describe machine-learning based predictive return models. However, in the 1990s, there were many exaggerated claims and hype about their potential value for forecasting stock returns that could completely revolutionize portfolio management. Consequently, they received considerable attention by the investment community and the media. It seems these claims never panned out.¹²

As a prerequisite for the adoption of a predictive return model, there are a number of key questions that a portfolio manager must address. These include:¹³

- What are the statistical properties of the model?
- How many predictor (explanatory) variables should be used in the model?

- What is the best statistical approach to estimate the model and is commercial software available for the task?
- How does one statistically test whether the model is valid?
- How can the consequences of errors in the choice of a model be mitigated?

The first and last questions rely on the statistical concepts that we described earlier. These questions are addressed in more technical-oriented equity investment management books.¹⁴ Consequently, we will limit our discussion in this entry to only the first question, describing the statistical properties of the four types of predictive return models. That is, we describe the fundamental statistical concepts behind these models and their economic meaning, but we omit the mathematical details.

Regressive Models

Regressive models of returns are generally based on linear regressions on factors. Factors are also referred to as predictors. Linear regression models are used in several aspects of portfolio management beyond that of return forecasting. For example, an equity analyst may use such models to forecast future sales of a company being analyzed.

Regressive models can be categorized as one of two fundamental kinds. The first is static regressive models. These models do not make predictions about the future but regress present returns on present factors. The second type is predictive regressive models. In such models future returns are regressed on present and past factors to make predictions. For both types of models, the statistical concepts and principles are the same. What differs is the economic meaning of each type of model.

Static Regressive Models

Static regressive models for predicting returns should be viewed as timeless relationships that are valid at any moment. They are not useful for predictive purposes because there is no time lag between the return and the factor. For example,

consider the empirical analogue of the CAPM as represented by the characteristic line given by the following regression model:

$$r_t - r_{ft} = \alpha_i + \beta_i [r_{Mt} - r_{ft}] + e_{it} \quad (1)$$

where

r_t = return on the stock in month t

r_{ft} = the risk-free rate in month t

r_{Mt} = the return on the market index (say S&P 500) in month t

e_t = the error term for the stock in month t

α and β = parameters for the stock to be estimated by the regression model

t = month ($t = 1, 2, \dots, T$)

The above model says that the conditional expectation of a stock's return at time t is proportional to the excess return of the market index at time t . This means that to predict the stock return at time $T + 1$, the portfolio manager must know the excess return of the market index at time $T + 1$, which is, of course, unknown at time $T + 1$. Predictions would be possible only if a portfolio manager could predict the excess return of the market index at time $T + 1$ (i.e., $r_{MT+1} - r_{fT+1}$).

There are also static multifactor models of return where the return at time t is based on the factor returns at time t . For example, suppose that there are N factors. Letting F_{nt} ($n = 1, 2, \dots, N$; $t = 1, 2, \dots, T$), then a regression model for a multifactor model for stock i (again dropping the subscript i for stock i) would be

$$\begin{aligned} r_t - r_{ft} = & \alpha + \beta_{F1}[r_{F1,t} - r_{ft}] \\ & + \beta_{F2}[r_{F2,t} - r_{ft}] + \dots \\ & + \beta_{FN}[r_{FN,t} - r_{ft}] + e_t \end{aligned} \quad (2)$$

where

r_t = return on the stock in month t

r_{ft} = the risk-free rate in month t

$r_{FN,t}$ = the return on factor N in month t

e_t = the error term for the stock in month t

α and β_{FN} 's = parameters for the stock to be estimated by the regression model
 $t = \text{month } (t = 1, 2, \dots, T)$

Thus, in order for a portfolio manager to build a portfolio or to compute portfolio risk measures using the above multifactor model for month $T + 1$, just as in the case of the characteristic line, some assumption about how to forecast the excess returns (i.e., $r_{FN,T+1} - r_{f,T+1}$) for each factor is required.

Predictive Regressive Models

In the search for models to predict returns, predictive regressive models have been developed. To explain predictive regressive models, consider some stock return and an assumed number of predictors. These predictors could be financial measures and market measures. A predictive linear regressive model assumes that the stock return at any given time t is a weighted average of its predictors at an earlier time plus a constant and some error. Hence, the information needed for predicting a stock's return does not require the forecasting of the predictor used in the regression model.

Predictive regressive models can also be defined by estimating a regression model where there are factors used as predictors at different lags. Such models, referred to as distributed lag models, have the advantage that they can capture the eventual dependence of returns not only on factors but also on the rate of change of factors. Here is the economic significance of such models. Suppose that a portfolio manager wants to create a predictive model based on, among other factors, "market sentiment." In practice, market sentiment is typically measured as a weighted average of analysts' forecasts. A reasonable assumption is that stock returns will be sensitive to the value of market sentiment but will be even more sensitive to changes in market sentiment. Hence, distributed lag models will be useful in this setting.

Linear Autoregressive Models

In a linear autoregressive model, a variable is regressed on its own past values. Past values are referred to as lagged values and when they are used as predictors in the model they are referred to as lagged variables. In the case of predictive return models, one of the lagged variables would be the past values of the return of the stock. If the model involves only the lagged variable of the stock return, it is called an *autoregressive model* (AR model). An AR model prescribes that the value of a variable at time t be a weighted average of the values of the same variable at times $t - 1, t - 2, \dots$, and so on (depending on number of lags) plus an error term. The weighting coefficients are the model parameters that must be estimated. If the model includes p lags, then p parameters must be estimated.

If there are other lagged variables in addition to the lagged variable representing the past values of the return on the stock included in the regression model, the model is referred to as a vector autoregressive model (VAR model). The model expresses each variable as a weighted average of its own lagged values plus the lagged values of the other variables. A VAR model with p lags is denoted by VAR(p) model. The benefit of a VAR model is that it can capture cross-autocorrelations; that is, a VAR model can model how values of a variable at time t are linked to the values of another variable at some other time. An important question is whether these links are causal or simply correlations.¹⁵

For a model to be useful, the number of parameters to be estimated needs to be small. In practice, the implementation of a VAR is complicated by the fact that such models can only deal with a small number of series. This is because when there is a large number of series—for example, the return processes for the individual stocks making up such aggregates as the S&P 500 Index—this would require a large number of parameters to be estimated. For example, if one wanted to model the daily returns

of the S&P 500 with a VAR model that included two lags, the number of parameters to estimate would be 500,000. To have at least as many data points as parameters, one would need at least four years of data, or 1,000 trading days, for each stock return process, which is $1,000 \times 500 = 500,000$ data points. Under these conditions, estimates would be extremely noisy and the estimated model would be meaningless.

Dynamic Factor Models

Unlike a VAR model, which involves regressing returns on factors but does not model the factors, a dynamic factor model assumes factors follow a VAR model and returns (or prices) are regressed on these factors. The advantage of such models is that unlike the large amount of data needed to estimate the large number of parameters in a VAR model, a dynamic factor model can significantly reduce the number of parameters to be estimated and therefore the amount of data needed.

Hidden-Variable Models

Hidden-variable models attempt to represent states of the market using hidden variables. Probably the best known hidden-variable model is the autoregressive conditional heteroscedasticity (ARCH) and generalized autoregressive conditional heteroscedasticity (GARCH) family. ARCH/GARCH models use an autoregressive process to model the volatility of another process. The result is a rich representation of the behavior of the model volatility.

Another category of hidden-variable models is the Markov switching–vector autoregressive (MS–VAR) family. These models do allow forecasting of expected returns. The simplest MS–VAR model is the Hamilton model.¹⁶ In economics, this model is based on two random walk models—one with a drift for periods of economic expansion and the other with a smaller drift for periods of economic recession. The switch between the two models is governed by a probability transition table that prescribes

the probability of switching from recession to expansion, and vice versa, and the probability of remaining in the same state.

IS FORECASTING MARKETS WORTH THE EFFORT?

In the end, all of this discussion leads to the question: What are the implications for portfolio managers and investors who are attempting or contemplating attempting building predictive return models? That is, how does this help portfolio managers and investors to decide if there is potentially sufficient benefit (i.e., trading profits and/or excess returns) in trying to extract information from market price data through quantitative modeling? There are three important points regarding this potential benefit.

The first, as stated by Fabozzi, Focardi, and Kolm (2006a, 11), is the following:

It is not true that progress in our ability to forecast will necessarily lead to a simplification in price and return processes. Even if investors were to become perfect forecasters, price and return processes might still exhibit complex patterns of forecastability in both expected values and higher moments, insofar as they might be martingales after dynamically adjusting for risk. No simple conclusion can be reached simply by assuming that investors are perfect forecasters: in fact, it is not true that the ability to forecast prices implies that prices are unpredictable random walks.

It is noteworthy that when the random walk hypothesis was first proposed in the academic community, it was the belief that the task of price forecasting efforts was a worthless exercise because prices were random walks. However, it seems reasonable to conclude that price processes will always be structured processes simply because investors are trying to forecast them. Modeling and sophisticated forecasting techniques will be needed to understand the risk-return trade-offs offered by the market.

The second point is that the idealized behavior of perfect forecasters does not have much to do with the actual behavior of real-world investors. The behavior of markets is the result,

not of perfectly rational market agents, but of the action of market agents with limited intelligence, limited resources, and subject to unpredictable exogenous events. Consequently, the action of market agents is a source of uncertainty in itself. As a result, there is no theoretical reason to maintain that the multivariate random walk is the most robust model.

Real-world investors use relatively simple forecasting techniques such as linear regressions. It is reasonable to believe that when real-world investors employ judgment, there is the possibility of making large forecasting errors. As the behavioral finance camp argues, the preoccupation with the idealized behavior of markets populated by perfect forecasters seems to be misguided. Theorists who defend the assumption that investors in the real world are perfect forecasters, believe that it is unreasonable to assume that investors make systematic mistakes. Proponents of this assumption claim that, on average, investors make correct forecasts.

However, the evidence suggests that this claim is not true. Investors can make systematic mistakes and then hit some boundary, the consequences of which can be extremely painful in terms of wealth accumulation as we saw in the late 1990s with the bursting of the technology, media, and telecommunications bubble. As Fabozzi, Focardi, and Kolm (2006a, 11) conclude:

A pragmatic attitude prevails. Markets are considered to be difficult to predict but to exhibit rather complex structures that can be (and indeed are) predicted, either qualitatively or quantitatively.

Finally, an important point is that predictability is not the only path to profitability/excess returns. Citing once again from Fabozzi, Focardi, and Kolm (2006a, 11–12):

If prices behaved as simple models such as the random walk model or the martingale, they could nevertheless exhibit high levels of persistent profitability. This is because these models are characterized by a fixed structure of expected returns. Actually, it is the time-invariance of expected returns coupled with the existence of risk premiums that makes these models unsuitable as long-term

models. . . . A model such as the geometric random walk model of prices leads to exponentially diverging expected returns. This is unrealistic in the long run, as it would lead to the concentration of all market capitalization in one asset. As a consequence, models such as the random walk model can only be approximate models over limited periods of time. This fact, in turn, calls attention to robust estimation methods. A random walk model is not an idealization that represents the final benchmark model: It is only a short-term approximation of what a model able to capture the dynamic feedbacks present in financial markets should be.

Hence, whether the random walk assumption is in fact the benchmark model of price processes must be addressed empirically. Yet, the view of portfolio managers is that markets offer patterns of predictability in returns, volatility (variance), and, possibly, higher moments. Because any such patterns might offer opportunities for realizing excess returns, a portfolio manager who ignores these patterns will be risking lost opportunities to enhance performance. As Fabozzi, Focardi, and Kolm (2006a, 24) state:

[S]imple random walk models with risk premiums are not necessarily the safest models. The joint assumptions that markets are unforecastable and that there are risk premiums is not necessarily the safest assumption.

KEY POINTS

- Despite the ongoing debate about the predictability of stock prices and returns, asset management firms have adopted statistical models of various levels of complexity for forecasting these values.
- The concept of forecastability rests on how one can forecast the future given the current information set known at that date.
- Prices or returns are said to be forecastable if the knowledge of the past influences our forecast of the future.
- The two beliefs that seem to be held in the investment community are (1) predictable processes allow investors to earn excess returns, and (2) unpredictable processes do not allow investors to earn excess returns.

- Predictable processes do not necessarily produce excess returns if they are associated with unfavorable risk, and unpredictable expectations can be profitable if the expected value is favorable.
- Probability theory is used in decision making to represent and measure the level of uncertainty.
- The absence of predictability means that the distribution of future returns does not change as a function of the present and past values of prices and returns.
- From this perspective, a price or return process is said to be predictable if its probability distributions depend on the current information set, and a price or return process is said to be unpredictable if its probability distributions do not vary over time. Using this concept of predictability, we can understand why prices and returns are difficult, perhaps even impossible, to predict.
- The key is that any prediction that might lead to an opportunity to generate a trading profit or an excess return tends to make that opportunity disappear. If stock return predictions are certain, then using simple arbitrage arguments would dictate that all stocks should have the same return. In fact, if stock returns could be predicted with certainty and if there were different returns, then investors would choose only those stocks with the highest returns.
- Because stock return forecasts are not certain, uncertain predictions are embodied in probability distributions.
- The problem faced by investors is whether general considerations of market efficiency are capable of determining the mathematical form of price or return processes. In particular, investors are interested in understanding if stock prices or returns are necessarily unpredictable.
- In solving this problem, the investor's objective is to shun models that permit unreasonable inferences. The following solutions have been proposed: (1) Returns fluctuate randomly around a given mean (i.e., returns follow multivariate random walks); (2) returns are a fair game (i.e., returns are martingales); and (3) returns are a fair game after adjusting for risk.
- Concepts from probability theory and statistics that are relevant in understanding return forecasting models are conditional probability, conditional expectation, independent and identically distributed random variables, strict white noise, martingale difference sequence, white noise, error terms, and innovations.
- An arithmetic random walk, a martingale, and a strict arithmetic random walk describe the stochastic process for returns and prices. If stock prices or returns follow an arithmetic random walk, the mean is linearly unpredictable but higher moments might be predictable.
- In the case of a martingale, the mean is unpredictable (linearly and nonlinearly), although higher moments might be predictable.
- If stock prices or returns follow a strict random walk, the mean, variance, and higher moments are all unpredictable.
- The statistical-based predictive return models used by portfolio managers make conditional forecasts of expected returns using the current information set: past prices, company information, and financial market information. These models are classified as regressive models, linear autoregressive models, dynamic factor models, and hidden-variable models.

NOTES

1. See Bernstein (2008).
2. The contributions of Bachelier are too exhaustive (and technical) to describe here. In addition to his study of the behavior of prices, his work in the area of random walks predated Albert Einstein's study of Brownian motion in physics by five years. His work in option pricing theory predated the well-known Black-Scholes option pricing model by 73 years.

3. See Samuelson (1965) and Fama (1965).
 4. See Bernstein (1998) for an account of the development of the concepts of risk and uncertainty from the beginning of civilization to modern risk management.
 5. The idea of probability as intensity of belief was introduced by Keynes (1921).
 6. The idea of probability as a relative frequency was introduced by von Mises (1921).
 7. See Rachev et al. (2007).
 8. More specifically, the presence of autocorrelation does not bias the estimated parameters of the model but results in biases in the standard errors of the estimated parameters, which are used in testing the goodness of fit of the model.
 9. Statements like this are intended as exemplifications but do not strictly embody sound econometric procedures. Adding lags has side effects, such as making estimations noisier, and cannot be used indiscriminately.

Factor Models for Portfolio Construction

Factor Models

GUOFU ZHOU, PhD

Frederick Bierman and James E. Spears Professor of Finance, Olin Business School,
Washington University in St. Louis

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Asset pricing models seek to estimate the relationship between the factors that drive asset expected return. The factors that drive the expected returns are referred to as risk factors. Two well-known asset pricing models returns are the capital asset pricing model and the arbitrage pricing theory. The relationship between risk factors and expected return in these two equilibrium models is based on various assumptions. In practice, multifactor models are estimated from observed asset returns and sophisticated statistical techniques are employed to estimate the exposure of an asset to each factor.

Given a set of assets or asset classes, an important task in the practice of investment management is to understand and estimate their expected returns and the associated risks. Factor models are widely used by investors to link the risk exposures of the assets to a set of known or unknown factors. The known factors can be economic or political factors, industry factors or country factors, and the unknown factors are those that best describe the dynamics of the asset returns in the factor models, but they are not directly observable or easily interpreted by investors and have to be estimated from the data.

Applications of the mean-variance analysis and portfolio selection theories in general require the estimation of expected asset returns and their covariance matrix. Those market participants who can identify those true factors that

drive asset returns should have much better estimates of the true expected asset returns and the covariance matrix, and hence should be able to form a much better portfolio than otherwise possible. Hence, a lot of research and resources are devoted to analyzing factor models in practice by the investment community. There is an intellectual “arms race” to find the best portfolio strategies to outperform competitors.

Factor model estimation depends crucially on whether the factors are *identified* (known) and unidentified (latent), and depend on the sample size and the number of assets. In addition, factor models can be used not only for explaining asset returns, but also for predicting future returns. In this entry, we review first the factor models in the case of known and latent factors in order to provide a big picture, and then discuss the details of estimation.

ARBITRAGE PRICING THEORY

One of the fundamental problems in finance is to explain the cross-section differences in asset expected returns. Specifically, what factors can explain the observed differences? Those factors that systematically affect the differences in expected returns are therefore the risks that investors are compensated for. Hence, the term “factors” is interchangeable with the term “risk factors.”

The *arbitrage pricing theory* (APT), formulated by Ross (1976), posits that expected returns of assets are linearly related to K *systematic factors*, and the exposure to these factors is measured by factor betas; that is,

$$E[\tilde{r}_i] = r_f + \gamma_1\beta_{i1} + \cdots + \gamma_K\beta_{iK} \quad (1)$$

where β_{ik} is the beta or risk exposure on the k -th factor, and γ_k is the factor risk premium, for $k = 1, 2, \dots, K$.

Technically, the APT assumes a K -factor model for the return-generating process, that is, the asset returns are influenced by K factors in the economy via linear regression equations,

$$\tilde{r}_{it} - r_{ft} = \alpha_i + \beta_{i1}\tilde{f}_{1t} + \cdots + \beta_{iK}\tilde{f}_{Kt} + \tilde{\varepsilon}_{it} \quad (2)$$

where $\tilde{f}_1, \tilde{f}_2, \dots, \tilde{f}_K$ are the systematic factors that affect all the asset returns on the left-hand side, $i = 1, 2, \dots, N$; and $\tilde{\varepsilon}_{it}$ is the asset specific risk. Note that we have placed a tilde sign (\sim) over the random asset returns, factors, and specific risks. By so doing, we distinguish between factors (random) and their realizations (data), which are important for understanding the estimation procedure below.

Theoretically, under the assumption of no arbitrage, the asset pricing relation of the APT as given by equation (1) must be true as demonstrated by Ross. There are two important points to note. First, the return-generating process as given by equation (2) is fundamentally different from the asset pricing relation. The return-generating process is a statistical model used to measure the risk exposures of the asset returns. It does not require drawing any economic con-

clusion, nor does it say anything about what the expected returns on the assets should be. In other words, the α_i 's in the return-generating process can statistically be any numbers. Only when the no-arbitrage assumption is imposed can one claim the APT, which says that the α_i 's should be linearly related to their risk exposures (betas).

Second, the APT does not provide any specific information about what the factors are. Nor does the theory make any claims on the number of factors. It simply assumes that if the returns are driven by the factors, and if the smart investors know the betas (via learning or estimating), then an arbitrage portfolio, which requires no investment but yields a positive return, can be formed if the APT pricing relation is violated in the market. Hence, in equilibrium if there are no arbitrage opportunities, we should not observe deviations from the APT pricing relation.

TYPES OF FACTOR MODELS

In this section we describe the different types of factor models.

Known Factors

The simplest case of factor models is where the K factors are assumed known or observable, so that we have time-series data on them. In this case, the K -factor model for the return-generating process as given by equation (2) is a multiple regression for each asset and is a multivariate regression if all of the individual regressions are pooled together. For example, if one believes that the gross domestic product (GDP) is the driving force for a group of stock returns, one would have a one-factor model,

$$\tilde{r}_{it} - r_{ft} = \alpha_i + \beta_{i1}\tilde{GDP}_t + \tilde{\varepsilon}_{it}$$

The above equation corresponds to equation (1) with $K = 1$ and $f_1 = \tilde{GDP}$. In practice, one can obtain time-series data on both the asset returns and GDP, and then one can estimate regressions to obtain all the parameters, including in particular the expected returns.

Another popular one-factor model is the market model regression

$$\tilde{r}_{it} - r_{ft} = \alpha_i + \beta_{i1}(\tilde{r}_{mt} - r_{ft}) + \tilde{\varepsilon}_{it}$$

where \tilde{r}_{mt} is the return on a stock market index.

To understand the covariance matrix estimation, it will be useful to write the K -factor model in matrix form,

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \tilde{\varepsilon}_t$$

or

$$\begin{bmatrix} \tilde{R}_{1t} \\ \vdots \\ \tilde{R}_{Nt} \end{bmatrix} = \begin{bmatrix} \alpha_1 \\ \vdots \\ \alpha_N \end{bmatrix} + \begin{bmatrix} \beta_{11} & \cdots & \beta_{1K} \\ \vdots & \ddots & \vdots \\ \beta_{N1} & \cdots & \beta_{NK} \end{bmatrix} \begin{bmatrix} \tilde{f}_{1t} \\ \vdots \\ \tilde{f}_{Kt} \end{bmatrix} + \begin{bmatrix} \tilde{\varepsilon}_{1t} \\ \vdots \\ \tilde{\varepsilon}_{Nt} \end{bmatrix}$$

where

- \tilde{R}_t = an N -vector of asset excess returns
- α = an N -vector of the alphas
- β = an $N \times K$ of betas or factor loadings
- \tilde{f}_t = a K -vector of the factors
- $\tilde{\varepsilon}$ = an N -vector of the model residuals.

For example, we can write a model with $N = 3$ assets and $K = 2$ factors as

$$\begin{bmatrix} \tilde{R}_{1t} \\ \tilde{R}_{2t} \\ \tilde{R}_{3t} \end{bmatrix} = \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} + \begin{bmatrix} \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \\ \beta_{31} & \beta_{32} \end{bmatrix} \begin{bmatrix} \tilde{f}_{1t} \\ \tilde{f}_{2t} \end{bmatrix} + \begin{bmatrix} \tilde{\varepsilon}_{1t} \\ \tilde{\varepsilon}_{2t} \\ \tilde{\varepsilon}_{3t} \end{bmatrix}$$

Taking covariance on both sides of equation (2), we have the return covariance matrix

$$\Sigma = \beta' \Sigma_f \beta + \Sigma_\varepsilon \quad (3)$$

where Σ_f is the covariance matrix of the factors, and Σ_ε is the covariance matrix of the residuals. Σ_f can be estimated by using the sample covariance matrix from the historical returns. This works for Σ_ε too if N is small relative to T . However, when N is large relative to T , the sample covariance matrix of the residuals will be poorly behaved.

Usually an additional assumption that the residuals are uncorrelated is imposed, so that Σ_ε becomes a diagonal matrix and can then be estimated by using the sample variances of the residuals. Plugging in the estimates of all the parameters into the right-hand side of equation (3), we obtain the covariance matrix needed for applying mean-variance portfolio analysis.

In the estimation of a multifactor model, it is implicitly assumed that the number of time series observations T is far greater than K , the number of factors. Otherwise, the regressions will perform poorly. For the case in which K is close to T , some special treatments are needed. This will be addressed later in this entry.

Examples of Multifactor Models with Known Factors

Before discussing latent factors, let's briefly describe four *multifactor models* where known factors are used: (1) the Fama-French three-factor model (Fama and French, 1993), (2) the MSCI Barra fundamental factor model, (3) the Burmeister-Ibbotson-Roll-Ross (BIRR) macroeconomic factor model (Burmeister, Roll, and Ross, 1994), and (4) the Barclay Group Inc. factor model. The first three are equity factor models and the last is a bond factor model.

The widely used Fama-French three-factor model is a special case of equation (1) with $K = 3$,

$$\tilde{r}_{it} - r_{ft} = \alpha_i + \beta_{im}(\tilde{r}_{mt} - r_{ft}) + \beta_{is} \tilde{SMB}_t + \beta_{ih} \tilde{HML}_t + \tilde{\varepsilon}_{it}$$

where \tilde{r}_{mt} , as before, is the return on a stock market index, \tilde{SMB}_t and \tilde{HML}_t are two additional factors. SMB_t (small minus big) is defined as the difference between the returns on diversified portfolios of small and big stocks (where small and big are measured in terms of stock market capitalization), and HML_t (high minus low) is defined as the difference between the returns on diversified portfolios of high and low book value-to-market value (B/M) stocks.

The introduction of these factors by Fama and French is to better capture the systematic variation in average return for typical portfolios than when using a stock market index alone. These factors are supported by empirical studies and are consistent with classifying stocks in terms of growth and value.

Fundamental factor models use company and industry attributes and market data as “descriptors.” Examples are price/earnings ratios, book/price ratios, estimated earnings growth, and trading activity. The estimation of a fundamental factor model begins with an analysis of historical stock returns and descriptors about a company. In the MSCI Barra model, for example, the process of identifying the factors begins with monthly returns for hundreds of stocks that the descriptors must explain. Descriptors are not the “*r* factors” but instead they are the candidates for risk factors. The descriptors are selected in terms of their ability to explain stock returns. That is, all of the descriptors are potential risk factors but only those that appear to be important in explaining stock returns are used in constructing risk factors. Once the descriptors that are statistically significant in explaining stock returns are identified, they are grouped into “risk indexes” to capture related company attributes. For example, descriptors such as market leverage, book leverage, debt-to-equity ratio, and company’s debt rating are combined to obtain a risk index referred to as “leverage.” Thus, a risk index is a combination of descriptors that captures a particular attribute of a company. For example, in the MSCI Barra fundamental multifactor model, there are 13 risk indices and 55 industry groups. The 55 industry classifications are further classified into sectors.

In a macroeconomic factor model, the inputs to the model are historical stock returns and observable macroeconomic variables. In the BIRR macroeconomic multifactor model, the macroeconomic variables that have been pervasive in explaining excess returns and which are therefore included in the market are

- *The business cycle*: Changes in real output that are measured by percentage changes in the index of industrial production.
- *Interest rates*: Changes in investors’ expectations about future interest rates that are measured by changes in long-term government bond yields.
- *Investor confidence*: Expectations about future business conditions as measured by changes in the yield spread between high- and low-grade corporate bonds.
- *Short-term inflation*: Month-to-month jumps in commodity prices, such as gold or oil, as measured by changes in the consumer price index.
- *Inflationary expectations*: Changes in expectations of inflation as measured by changes in the short-term, risk-free nominal interest rate.

Additional variables, such as the real GDP growth and unemployment rates, are also among the macroeconomic factors used by asset managers in other macroeconomic multifactor models. Moreover, some asset managers also have identified technical variables, such as trading volume and market liquidity, as factors.

The Barclay Group Inc. (BGI) bond factor model (previously the Lehman bond factor model) uses two categories of systematic risk factors: term structure factors and non-term structure risk factors. The former include changes in the level of interest and changes in the shape of the yield curve. The non-term structure factors are sector risk, credit risk, optionality risk, and a series of risks associated with investing in mortgage-backed securities.

The search for factors is a never-ending task of asset managers. In practice, many popular investment software packages use dozens of factors. Some academic studies, such as Ludvigson and Ng (2007), use hundreds of them.

Latent Factors

While some applications use observed factors, some use entirely latent factors, that is, the view

that the factors f_t in the K -factor model,

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \tilde{\varepsilon}_t$$

are not directly observable. An argument for the use of latent factors is that the observed factors may be measured with errors or have been already anticipated by investors. Without imposing what f_t are from our likely incorrect belief, we can statistically estimate the factors based on the factor model and data.

It is important to understand that in the field of statistics, there is statistical methodology known as “factor analysis” and the model generated is referred to as a “factor model.” Factor models as used by statisticians are statistical models that try to explain complex phenomena through a small number of basic causes or factors with the factors being latent. Factor models as used by statisticians serve two main purposes: (1) They reduce the dimensionality of models to make estimation possible, and/or (2) they find the true causes that drive data. In our discussion of multifactor models, we are using the statistical tool of factor analysis to try to determine the *latent factors* driving asset returns.

While the estimation procedures for determining the set of factors will be discussed in the next section, it will be useful to know some of the properties of the factor model here. The first property is that the factors are not uniquely defined in the model, but all sets of factors are linear combinations of each other. This is because if \tilde{f}_t is a set of factors, then, for any $K \times K$ invertible matrix A , we have

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \tilde{\varepsilon}_t = \alpha + (\beta A^{-1})(A\tilde{f}_t) + \tilde{\varepsilon}_t \quad (4)$$

which says that if \tilde{f}_t with regression coefficients β (known as adding factor loadings in the context of factor models) explains asset returns well, so does $\tilde{f}_t^* = A\tilde{f}_t$ with loadings βA^{-1} . The linear transformation of $\tilde{f}_t, \tilde{f}_t^*$, is also known as a *rotation* of f_t .

The second property is that we can assume all the factors have zero mean (i.e., $E[\tilde{f}_t] = 0$). This

is because if $\mu_f = E[f_t]$, then the factor model can be written as

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \tilde{\varepsilon}_t = (\alpha - \beta \mu_f) + \beta(\tilde{f}_t - \mu_f) + \tilde{\varepsilon}_t \quad (5)$$

If we rename $\alpha - \beta \mu_f$ as the new alphas, and $f_t - \mu_f$ as the new factors, then the new factors will have zero means, and the new factor model is statistically the same as the old one. Hence, without loss of generality, we will assume that the mean of the factors are zeros in our estimation in the next section.

Note that the return covariance matrix formula, equation (3) or

$$\Sigma = \beta' \Sigma_f \beta + \Sigma_\varepsilon \quad (6)$$

holds regardless of whether the factors are observable or latent. However, through factor rotation, we can make a new set of factors so as to have the identity covariance matrix. In this case with $\Sigma_f = I_K$, we say that the factor model is standardized, and the covariance equation then simply becomes

$$\Sigma = \beta' \beta + \Sigma_\varepsilon \quad (7)$$

In general, Σ_ε can have nonzero off-diagonal elements, implying that the residuals are correlated. If we assume that the residuals are uncorrelated, then Σ_ε becomes a diagonal matrix, and the factor model is known as a strict factor model. If we assume further that Σ_ε has equal diagonal elements, i.e., $\Sigma_\varepsilon = \sigma^2 I_N$ for some $\sigma > 0$ with I_N an N identity matrix, then the factor model is known as a normal factor model.

Both Types of Factors

Rather than taking the view of only observable factors or only latent factors, we can consider a more general factor model with both types of factors,

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \beta_g \tilde{g}_t + \tilde{\varepsilon}_t \quad (8)$$

where \tilde{f}_t is a K -vector of latent factors, \tilde{g}_t is an L -vector of observable factors, and β_g are the betas associated with \tilde{g}_t . This model makes intuitive sense. If we believe a few fundamental or macroeconomic factors are the driving forces, they can be used to create the \tilde{g}_t vector. Since we may not account for all the possible factors, we need to add K unknown factors, which are to be estimated from the data.

The estimation of the above factor model given by equation (8) usually involves two steps. In the first step, a regression of the asset returns on the known factors is run in order to obtain $\hat{\beta}_g$, an estimate of β_g . This allows us to compute the residuals,

$$\hat{u}_t = R_t - \hat{\beta}_g g_t \quad (9)$$

that is, the difference of the asset returns from their fitted values by using the observed factors for all the time periods. Then, in the second step, a factor estimation approach is used to estimate the latent factors for \hat{u}_t ,

$$\tilde{u}_t = \alpha + \beta \tilde{f}_t + \beta_g \tilde{g}_t + \tilde{v}_t \quad (10)$$

where \tilde{u}_t is the random differences whose realized values are \hat{u}_t . The estimation method for this model is the same as estimating a latent factor model and will be detailed in the next section. With the factor estimates, we can treat the latent factors as known, and then use equation (8) to determine the expected asset returns and covariance matrix.

Predictive Factor Models

An important feature of factor models is that they use time t factors to explain time t returns. This is to estimate the long-run risk exposures of the assets, which are useful for both risk control and portfolio construction. On the other hand, portfolio managers are also very concerned about time-varying expected returns. In this case, they often use a predictive factor model such as the following to forecast the returns,

$$\tilde{R}_{t+1} = \alpha + \beta \tilde{f}_t + \beta_g \tilde{g}_t + \tilde{\varepsilon}_t \quad (11)$$

where as before \tilde{f}_t and \tilde{g}_t are the latent and observable factors, respectively. The single difference is that the earlier \tilde{R}_t is now replaced by \tilde{R}_{t+1} . Equation (11) uses time t factors to forecast future return \tilde{R}_{t+1} .

Computationally, the estimation of the predictive factor model is the same as for estimating the standard factor models. However, it should be emphasized that the regression R^2 , a measure of model fitting, is usually very good in the explanatory factor models. In contrast, if a predictive factor model is used to forecast the expected returns of various assets, the R^2 rarely exceeds 2%. This simply reflects the fact that assets returns are extremely difficult to predict in the real world. For example, Rapach, Strauss, Tu, and Zhou (2009) find that the R^2 are mostly less than 1% when forecasting industry returns using a variety of past economic variables and past industry returns.

FACTOR MODEL ESTIMATION

In this section, we provide first a step-by-step procedure for estimating the factor model based on the popular and implementable approach, *principal components analysis* (PCA), to which a detailed and intuitive introduction is provided in the last section of this entry. PCA is a statistical tool that is used by statisticians to determine factors with statistical learning techniques when factors are not observable. That is, given a variance-covariance matrix, a statistician can determine factors using the technique of PCA. Then, after learning the computational procedure, we provide an application to identify three factors for bond returns. Finally, we outline some alternative procedures for estimating the factor models and their extensions.

Computational Procedure

By our use of latent models, we need to consider only how to estimate the latent factors \tilde{f}_t from

the K -factor model,

$$\tilde{Y}_t = \beta \tilde{f}_t + \tilde{\varepsilon}_t \quad (12)$$

where

$$E(\tilde{f}_t) = 0, \quad E[\tilde{Y}_t] = 0$$

This version of the factor model is obtained in two steps. We de-mean first the factor f_t so that the alphas are the expected returns of the assets. Second, we de-mean again the asset returns. In other words, we let $\tilde{Y}_t = \tilde{R}_t - \alpha$.

In practice, suppose that we have return data on N risky assets over T time periods. Then the realizations of the random variable \tilde{Y}_t can be summarized by a matrix,

$$Y = \begin{pmatrix} Y_{11} & Y_{21} & \cdots & Y_{N1} \\ \vdots & \vdots & \vdots & \vdots \\ Y_{1T} & Y_{2T} & \cdots & Y_{NT} \end{pmatrix} \quad (13)$$

where each row is the N asset returns subtracting from their sample means at time t for $t = 1, 2, \dots, T$. Our task is to estimate the realizations (unobserved) on the K factors, \tilde{f}_t , over the T periods,

$$F = \begin{pmatrix} F_{11} & F_{21} & \cdots & F_{K1} \\ \vdots & \vdots & \vdots & \vdots \\ F_{1T} & F_{2T} & \cdots & F_{KT} \end{pmatrix} \quad (14)$$

We will now apply PCA estimation methodology.

There are two important cases, each of which calls for a different way of applying PCA. The first case is the one of traditional factor analysis in which N is treated as fixed, and T is allowed to grow. We will refer to this case as the “fixed N ” below. The second case is when N is allowed to grow but T is either fixed or allowed to grow. We will refer to this case simply as “large N .”

Case 1: Fixed N

In the case of fixed N , we have a relatively smaller number of assets and a relatively large sample size. Then the covariance matrix of the asset returns, which is the same as the covariance matrix of \tilde{Y}_t , can be estimated by the sam-

ple covariance matrix,

$$\Psi = \frac{Y'Y}{T} \quad (15)$$

which is an N by N matrix since Y is T by N . For example, if we think there are K (say $K = 5$) factors, we can use standard software to compute the first K eigenvectors of Ψ corresponding to the first K largest eigenvalues of Ψ , each of which is an N vector. Let $\hat{\beta}$ be the N by K matrix formed by these K eigenvectors. Then $\hat{\beta}$ will be an estimate of β . Based on this, the factors are estimated by

$$\hat{F}_t = Y_t \hat{\beta}, \quad t = 1, 2, \dots, T \quad (16)$$

where Y_t is the t -th row of Y , and \hat{F}_t is the estimate of F_t , the t -th row of F . The \hat{F}_t 's are the estimated realizations of the first K factors. Seber (1984) explains why the \hat{F}_t 's are good estimates of the true and unobserved factor realizations. However, theoretically, they, though close, will not necessarily converge to the true values, unless the factor model is normal, as T increases. Nevertheless, despite this problem, this procedure is widely used in practice.

Case 2: Large N

In the case of large N , we have a large number of assets. We now form a new matrix based on the product of Y with Y' ,

$$\Omega = \frac{YY'}{T} \quad (17)$$

which is a T by T matrix since Y is T by N . Given K , we use standard software to compute the first K eigenvectors of Ω corresponding to the first K largest eigenvalues of Ω , each of which is a T vector. Letting \hat{F} be the T by K matrix formed by these K eigenvectors, the PCA says that \hat{F} is an estimate of the true and unknown factor realizations F of equation (14), up to a linear transformation. Connor and Korajczyk (1986) provided the first study in the finance literature to apply the PCA as described above. The method is also termed “asymptotic PCA” since it allows the number of assets to increase without bound. In contrast, traditional PCA

keeps N fixed, while allowing the number of time periods, T , to be large.

Theoretically, if the true factor model is the strict factor model or is not much too different from it (i.e., the residual correlations are not too strong), Bai (2003) shows that \hat{F} converges to F up to a linear transformation when both T and N increase without limit. The estimation errors are of order the larger of $1/T$ or $1/\sqrt{N}$, and converge to zero as both T and N grow to infinity. However, when T is fixed, we need a stronger assumption that the true factor model is close to a normal model, then the estimation errors are of order of $1/\sqrt{N}$. Intuitively, at each time t , given that there are only a few factors to pricing so many assets, we should have enough information to back out the factors accurately.

Based on the estimated factors, the factor loadings are easily estimated from equation (12). For example, we can obtain the loadings for each asset by estimating the standard ordinary least squares (OLS) regression of the asset returns on the factors. Mathematically, this is equivalent to computing all the loadings from the formula

$$\hat{\beta}' = (\hat{F}'\hat{F})^{-1}\hat{F}'X \quad (18)$$

Under the same conditions above, $\hat{\beta}$ also converges to β up to a linear transformation.

The remaining question is how to determine K . In practice, this may be determined by trial and error depending on how different K 's perform in model fitting and in meeting the objectives where the model is applied. From an econometrics perspective, there is a simple solution in Case 2. Bai and Ng (2002) provide a statistical criterion

$$IC(K) = \log(V(K)) + K \left(\frac{N+T}{NT} \right) \log \left(\frac{NT}{N+T} \right) \quad (19)$$

where

$$V(K) = \sum_{i=1}^N \sum_{t=1}^T (Y_{it} - \hat{\beta}_{i1}\hat{f}_{1t} - \hat{\beta}_{i2}\hat{f}_{2t} - \dots - \hat{\beta}_{iK}\hat{f}_{Kt})^2 \quad (20)$$

For a given K , $V(K)$ is the sum of the fitted squared residual errors of the factor model across both asset and time. This is a measure of model fitting. The smaller the $V(K)$, the better the K -factor model in explaining the asset returns. So we want to choose such a K that minimizes $V(K)$. However, the more the factors, the smaller the $V(K)$, but at a cost of estimating more factors with greater estimation errors. Hence, we want to penalize too many factors. This is the same as the case in linear regressions where we also want to penalize too many regressors. The second term in equation (19) plays this role. It is an increasing function of K . Therefore, the trade-off between model fitting and estimation errors requires us to minimize the $IC(K)$ function. Theoretically, assuming that the factor model is indeed true for some fixed K^* , Bai and Ng show that the K that minimizes $IC(K)$ will converge to K^* as either N or T or both increase to infinity.

An Application to Bond Returns

To illustrate the procedure, consider an application of the PCA factor analysis to the excess returns on Treasury bonds with maturities 12, 18, 24, 30, 36, 42, 48, 54, 60, 120, and beyond 120 months. Hence, there are $N = 11$ assets. With monthly data from January 1980 to December 2008, available from the Center for Research in Security Prices of the University of Chicago's Graduate School of Business, we have a sample size of $T = 348$. Since N is small relative to T , this is a case of the fixed N .

Now

$$\Psi = \frac{Y'Y}{348}$$

is an 11 by 11 matrix. We can easily compute its eigenvalues and eigenvectors. The largest three eigenvalues are

$$(\lambda_1, \lambda_2, \lambda_3) = 10^{-2}(0.2403, 0.133, 0.012)$$

whose sum is more than 99% of the sum of all the eigenvalues. Thus, it is enough to consider $K = 3$ factors and use the first three

Table 1 Factor Loadings and Explanatory Power

	β_1	β_2	β_3	R^2 (F_1)	R^2 (F_1 and F_2)	R^2 (all three)
12 month	0.0671	-0.1418	0.4046	0.67	0.80	0.96
18 month	0.1118	-0.2057	0.4227	0.79	0.84	0.99

60 month	0.3368	-0.1819	-0.3246	0.97	0.98	0.99
120 month	0.4038	0.0426	-0.1507	0.99	0.99	0.99
Over 120	0.5966	0.7173	0.2394	0.92	0.93	1.00

eigenvectors, PCAs, as proxies for the factors. Denote them as F_1 , F_2 and F_3 .

Consider now the regression of the 11 excess bond returns on the three factors,

$$R_{it} = \alpha_i + \beta_{i1}F_{1t} + \beta_{i2}F_{2t} + \beta_{i3}F_{3t} + \varepsilon_{it}$$

where $i = 1, 2, \dots, 11$. The regression R^2 s of using all the factors for each of the assets are reported in the last column of Table 1. All but one is 99% or above, confirming the eigenvalue analysis that three factors are sufficient, which explains almost all the variations of the bond returns. However, when only the first two are used, the R^2 s are smaller, but the minimum is still over 80%. When only the first factor is used, the R^2 s range from 67% on the first bond return to 99% on the 10th. Overall, the PCA factors are effective in explaining the asset returns.

The factor loadings or regression coefficients on the factors are also reported in Table 1. It is interesting that the loadings on the first factor are all positive. This implies that a positive realization of F_1 will have a positive effect on the returns of all the bonds. It is, however, clear that F_1 affects long-term bonds more than short-term bonds. As an approximation, F_1 is usually interpreted as a *level effect* or *parallel effect* that roughly shifts the returns on bonds across maturity.

The second factor, however, has a different pattern from the first. A positive realization

of F_1 will have a negative effect on short-term bonds and a positive effect on the long-term ones. This is equivalent to an increase in the slope of the bond returns across maturity (known as yield curve). Therefore, F_2 is commonly identified as a steepness factor.

Finally, a positive realization of F_3 will have a positive effect on both short- and long-term bonds, but a negative effect on the intermediate ones. Hence F_3 is usually interpreted as a curvature factor. Litterman and Scheinkman (1991) appears to have been one of the first to to apply the PCA to study bond returns and to have identified the above three factors. Although the data we used here are different, the three factors we computed share the same properties as those identified by them.

Alternative Approaches and Extensions

The standard statistical approach for estimating the factor model is the maximum likelihood (ML) method. Consider the factor model given by equation (12) where $E(\tilde{f}_t) = 0$, $E[\tilde{Y}_t] = 0$. The de-meaned returns and standardized factors are usually assumed to have normal distributions.

In addition, the factors are usually standardized so that $\Sigma_f = I_K$, and the residuals are assumed uncorrelated so that Σ_ε is diagonal. Then the log likelihood function, as the log density

function of the returns, is

$$\log L(\beta, \Sigma_\varepsilon) = -\frac{NT}{2} \log(2\pi) - \frac{T}{2} \log |\beta' \beta + \Sigma_\varepsilon| - \frac{1}{2} \sum_{t=1}^T Y_t (\beta' \beta + \Sigma_\varepsilon)^{-1} Y_t \quad (21)$$

The ML estimator of the parameters β and Σ_ε are those values that maximize the log likelihood function. Since β enters into the function in a complex nonlinear way, an analytical solution to the maximization problem is a very difficult problem. Numerically, it is still difficult if maximizing $\log L(\beta, \Sigma_\varepsilon)$ directly.

There is, however, a data-augmentation technique known as the *expectation maximization* (EM) *algorithm* that can be applied (see Lehmann and Modest, 1998). The EM algorithm can be effective in numerically solving the earlier maximization problem. The idea of the EM algorithm is simple. The key difficulty here is that the factors are unobserved. But conditional on the parameters and the factor model, we can learn them. Consider now that given the factors \tilde{f}_t , the log likelihood function conditional on f_t is

$$\log L_c(\beta, \Sigma_\varepsilon) = -\frac{NT}{2} \log(2\pi) - \frac{T}{2} \log |\Sigma_\varepsilon| - \frac{1}{2} \sum_{t=1}^T (Y_t - \beta f_t)' \Sigma_\varepsilon^{-1} (Y_t - \beta f_t) \quad (22)$$

Because it is conditional on f_t , the factor model is the usual linear regression. In other words, integrating out f_t from equation (22) yields the unconditional $\log L(\beta, \Sigma_\varepsilon)$. The beta estimates conditional on f_t are straightforward. They are the usual OLS regression coefficients, and the estimates for Σ_ε are the residual variances.

On the other hand, conditional on the parameters, we can learn the factors by using their conditional expected values obtained easily from their joint distribution with the returns. Hence, we can have an iterative algorithm. Starting from an initial guess of the factors, we maximize

the conditional likelihood function to obtain the OLS β and Σ_ε estimates, which is the M-step of the EM algorithm. Based on these estimates, we update a new estimate of f_t using their expected value. This is the EM algorithm's E-step. Using the new f_t , we learn new estimates of β and Σ_ε in the M-step. With the new estimates, we can again update the f_t . Iterating between the EM steps, the limits converge to the unconditional ML estimate and the factor estimates converge to the true ones.

As an alternative to the ML method, Geweke and Zhou (1996) propose a Bayesian approach, which treats all parameters as random variables. It works in a way similar to the EM algorithm. Conditional on parameters, we learn the factors, and conditional on the factors, we learn the parameters. Iterating after a few thousand times, we learn the entire joint distribution of the factors and parameters, which are all we need in a factor model. The advantage of the Bayesian approach is that it can incorporate prior information and can provide exact inference. In contrast, the ML method cannot use any priors, nor can it obtain the exact standard errors of both parameters and functions of interest due to the complexity of the factor model. Nardari and Scuggs (2007) extend the Bayesian approach to allow a more general model in which the covariance matrix can vary over time and the APT restrictions can be imposed.

Finally, we provide two important extensions of the factor model that are useful in practice. Note that the factors we discussed thus far assume identical and independently distributed returns and factors. These are known as *static factor models*. The first extension is *dynamic factor models*, which allow the factors to evolve over time according to a vector autoregression,

$$\tilde{f}_t = A_1 \tilde{f}_{t-1} + A_2 \tilde{f}_{t-2} + \cdots + A_m \tilde{f}_{t-m} + \tilde{v}_t \quad (23)$$

where the A 's are the regression coefficient matrices, m is the order of the autoregression that

determines how far past factor realizations still affect today's realizations, and v_t is the residual. In practice, many economic variables are highly persistent, and hence it will be important to incorporate this as above. (See Amengual and Watson [2007] for a discussion of estimation for dynamic factor models.)

The second extension is to allow the case with a large number of factors. Consider our earlier factor model

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \beta_g \tilde{g}_t + \tilde{\varepsilon}_t \quad (24)$$

where \tilde{f}_t is a K vector of latent factors, \tilde{g}_t is an L vector of observable factors. The problem now is that L is large, about 100 or 200, for instance. This requires at least a few hundred or more time series observations for the regression of R_t on g_t to be well behaved, and this can cause a problem due to the lack of long-term time series data or due to concerns of stationarity. The idea is to break \tilde{g}_t into two sets, \tilde{g}_{1t} and \tilde{g}_{2t} , with the first having a few key variables and the second having the rest. We then consider the modified model

$$\tilde{R}_t = \alpha + \beta \tilde{f}_t + \beta_{g1} \tilde{g}_{1t} + \beta_{h1} \tilde{h}_t + \tilde{\varepsilon}_t \quad (25)$$

where $\tilde{h}(t)$ has a few variables too that represent a few major driving forces that summarize the potentially hundreds of variables of \tilde{g}_{2t} via another factor model,

$$\tilde{g}_{2t} = B \tilde{h}_t + \tilde{u}_t \quad (26)$$

where \tilde{u}_t is the residual. This second factor model provides a large dimension reduction that transforms the hundreds of variables into a few, which can be estimated by the PCA. In the end, we have only a few factors in equation (25), making the analysis feasible based on the methods we discussed earlier. Ludvigson and Ng (2007) appear to be the first to apply such a model in finance. They find that the model can effectively incorporate a few hundred variables so as to make a significant difference in understanding stock market predictability.

USE OF PRINCIPAL COMPONENTS ANALYSIS

Principal components analysis (PCA) is a widely used tool in finance. It is useful not only for estimating factor models as explained in this entry, but also for extracting a few driving variables in general out of many for the covariance matrix of asset returns. Hence, it is important to understand the statistical intuition behind it. To this end, we provide a simple introduction to it in the last section of the entry.

Perhaps the best way to understand the PCA is to go through an example in detail. Suppose there are two risky assets, whose returns are denoted by \tilde{r}_1 and \tilde{r}_2 , with covariance matrix

$$\Sigma = \begin{bmatrix} \sigma_1^2 & \sigma_{12} \\ \sigma_{21} & \sigma_2^2 \end{bmatrix} = \begin{bmatrix} 2.05 & 1.95 \\ 1.95 & 2.05 \end{bmatrix}$$

That is, we assume that they have the same variances of 2.05 and covariance of 1.95. Our objective is to find a linear combination of the two assets so that it has a large component in the covariance matrix, which will be clear below. For notation brevity, we assume first that the expected returns are zeros; that is,

$$E[\tilde{r}_1] = 0, \quad E[\tilde{r}_2] = 0$$

and will relax this assumption later.

Recall from linear algebra that we call any vector $(a_1, a_2)'$ satisfying

$$\Sigma \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \lambda \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

an eigenvector of Σ , and the associated λ the eigenvalue. In our example here, it is easy to verify that

$$\begin{bmatrix} 2.05 & 1.95 \\ 1.95 & 2.05 \end{bmatrix} \cdot \begin{pmatrix} 1 \\ 1 \end{pmatrix} = 4 \times \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

and

$$\begin{bmatrix} 2.05 & 1.95 \\ 1.95 & 2.05 \end{bmatrix} \cdot \begin{pmatrix} 1 \\ -1 \end{pmatrix} = 0.1 \times \begin{pmatrix} 1 \\ -1 \end{pmatrix}$$

so 4 and 0.1 are the eigenvalues, and $(1, 1)'$ and $(1, -1)'$ are the eigenvectors.

In practice, computer software is available to compute the eigenvalue and eigenvectors of any covariance matrix. The mathematical result is that for a covariance matrix of N assets, there are exactly N different eigenvectors and N associated positive eigenvalues (these eigenvalues can be equal in some cases). Moreover, the eigenvectors are orthogonal to each other; that is, their inner product or vector product is zero. In our example, it is clear that

$$(1, 1)' \cdot \begin{pmatrix} 1 \\ -1 \end{pmatrix} = 1 - 1 = 0$$

It should be noted that the eigenvalue associated with each eigenvector is unique, but any scale of the eigenvector remains an eigenvector. In our example, it is obvious that a double of the first eigenvector, $(2, 2)'$, is also an eigenvector. However, the eigenvectors will be unique if we standardize them, making the sum of the elements 1. In our example,

$$A_1 = \begin{bmatrix} 1/\sqrt{2} \\ 1/\sqrt{2} \end{bmatrix}, \quad A_2 = \begin{bmatrix} 1/\sqrt{2} \\ -1/\sqrt{2} \end{bmatrix}$$

are the standardized eigenvectors, which are obtained by scaling the earlier eigenvectors by $1/\sqrt{2}$. These are indeed standardized, since

$$A_1' A_1 = (1/\sqrt{2})^2 + (1/\sqrt{2})^2 = 1$$

$$A_2' A_2 = (1/\sqrt{2})^2 + (-1/\sqrt{2})^2 = 1$$

Now let us consider two linear combinations (or portfolios without imposing the weights summing to 1) of the two assets whose returns are \tilde{r}_1 and \tilde{r}_2 ,

$$\tilde{P}_1 = \frac{1}{\sqrt{2}}\tilde{r}_1 + \frac{1}{\sqrt{2}}\tilde{r}_2 = A_1' \tilde{R}$$

$$\tilde{P}_2 = \frac{1}{\sqrt{2}}\tilde{r}_1 - \frac{1}{\sqrt{2}}\tilde{r}_2 = A_2' \tilde{R}$$

where $\tilde{R} = (\tilde{r}_1, \tilde{r}_2)'$. Both \tilde{P}_1 and \tilde{P}_2 are called the *principal components* (PCs). There are three important and interesting mathematical facts about the PCs.

- *Fact 1.* The variances of the PCs are exactly equal to the eigenvalues corresponding to the eigenvectors used to form the PCs.

That is,

$$\text{Var}(\tilde{P}_1) = 4$$

$$\text{Var}(\tilde{P}_2) = 1$$

Note that the two PCs are random variables since they are the linear combination of random returns. So, their variances are well defined. The equalities to the eigenvalues can be verified directly.

- *Fact 2.* The returns can also be written as linear combinations of the PCs.

The PCs are defined as linear combinations of the returns. Inverting them, the returns are linear functions of the PCs, too. Mathematically, $\tilde{P} = A\tilde{R}$, and so $\tilde{R} = A^{-1}\tilde{P}$. Since A is orthogonal, $A^{-1} = A'$, thus $\tilde{R} = A'\tilde{P}$. That is, we have

$$\begin{aligned} \tilde{r}_1 &= \frac{1}{\sqrt{2}}\tilde{P}_1 + \frac{1}{\sqrt{2}}\tilde{P}_2 \\ \tilde{r}_2 &= \frac{1}{\sqrt{2}}\tilde{P}_1 - \frac{1}{\sqrt{2}}\tilde{P}_2 \end{aligned} \quad (26)$$

- *Fact 3.* The asset return covariance matrix can be decomposed as the sum of the products of eigenvalues with the cross products of eigenvectors.

Mathematically, it is known that

$$\begin{aligned} \Sigma &= [A_1, A_2] \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} [A_1, A_2]' \\ &= \lambda_1 A_1 A_1' + \lambda_2 A_2 A_2' = 4A_1 A_1' + 0.1A_2 A_2' \end{aligned}$$

which is also easy to verify in our example. The economic interpretation is that the total risk profile of the two assets, as captured by their covariance matrix, is a sum of two components. The first component is determined by the first PC, and the second is determined by the second PC. In other words, in the return linear combinations, equation (26), if we ignore P_2 , we will get only $\lambda_1 A_1 A_1'$, the first component in the covariance matrix decomposition, and only the

second if we ignore P_1 . We obtain the entire Σ if we ignore neither.

The purpose of the PCA is finally clear. Since 4 is 40 times as big as 0.1, the second component in the Σ decomposition has little impact, and hence may be ignored. Then, ignoring \tilde{P}_2 , we can write the returns simply as, based on equation (26),

$$\begin{aligned}\tilde{r}_1 &\approx (1/\sqrt{2})\tilde{P}_1 \\ \tilde{r}_2 &\approx (1/\sqrt{2})\tilde{P}_1\end{aligned}$$

This says that we can reduce the analysis of \tilde{r}_1 and \tilde{r}_2 by analyzing simple functions of \tilde{P}_1 . In this example, the result tells us that the two assets are almost the same. In practice, there may be hundreds of assets. By using PCA, we can reduce the dimensionality of the problem substantially to an analysis of perhaps a few, say five, PCs.

In general, when there are N assets with return $\tilde{R} = (\tilde{r}_1, \dots, \tilde{r}_N)'$, computer software can be used to obtain the N eigenvalues and N standardized eigenvectors. Let $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_N \geq 0$ be the N eigenvalues in decreasing order, and $A_i = (a_{i1}, a_{i2}, \dots, a_{iN})'$ be the standardized eigenvector associated with λ_i , and A be an $N \times N$ matrix formed by the all the eigenvectors. Then, the i -th PC is defined as $\tilde{P}_i = A_i' \tilde{R}$, all of which can be computed in matrix form,

$$\tilde{P} = \begin{bmatrix} \tilde{P}_1 \\ \tilde{P}_2 \\ \vdots \\ \tilde{P}_N \end{bmatrix} = \begin{bmatrix} A_1' \tilde{R} \\ A_2' \tilde{R} \\ \vdots \\ A_N' \tilde{R} \end{bmatrix} = A' \tilde{R} \quad (27)$$

The decomposition for Σ is

$$\begin{aligned}\Sigma &= [A_1, \dots, A_N] \begin{bmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \lambda_N \end{bmatrix} [A_1, \dots, A_N]' \\ &= \lambda_1 A_1 A_1' + \lambda_2 A_2 A_2' + \dots + \lambda_N A_N A_N'\end{aligned}$$

It is usually the case that, for some K , the first K eigenvalues are large, and the rest are too small and can then be ignored. In such situations, based on the first K PCs, we can approxi-

mate the asset returns by

$$\begin{aligned}\tilde{r}_1 &\approx a_{11}\tilde{P}_1 + a_{12}\tilde{P}_2 + \dots + a_{1K}\tilde{P}_K, \\ \tilde{r}_2 &\approx a_{21}\tilde{P}_1 + a_{22}\tilde{P}_2 + \dots + a_{2K}\tilde{P}_K, \\ &\vdots \\ \tilde{r}_N &\approx a_{N1}\tilde{P}_1 + a_{N2}\tilde{P}_2 + \dots + a_{NK}\tilde{P}_K\end{aligned} \quad (28)$$

In most studies, the K PCs may be interpreted as K factors that (approximately) derive the movements of all the N returns. Our earlier example is a case with $K = 1$ and $N = 2$.

In the above PCA discussion, the expected returns of the asset are assumed to be zero. If they are nonzero and given by a vector $(\mu_1, \mu_2, \dots, \mu_N)'$, Σ will remain the same, and so will the eigenvalues and eigenvectors. However, in this case we need to replace all the \tilde{r}_i 's in equation (27) by $\tilde{r}_i - \mu_i$'s and add μ_i 's on the right-hand side of equation (28). The interpretation will be, of course, the same as before.

In Case 1 of the factor model estimation (i.e., known or observable factors) discussed in the entry, the K PCs clearly provide a good approximation of the first K factors since they explain the asset variations the most given K . Moreover, in either Case 1 or Case 2 (latent factors), the PCA is equivalent to minimizing the model errors, as given by equation (20), by choosing both the loadings and factors, and hence the solution should be close to the true factors and loadings.

KEY POINTS

- The arbitrage pricing theory is a general multifactor model for pricing assets. The theory does not provide any specific information about what the factors are. Moreover, the APT does not make any claims on the number of factors either.
- The APT asserts that only taking the systematic risks is rewarded.
- The APT simply assumes that if the returns are driven by the factors, and if investors know the betas for the factors, then an arbitrage portfolio, which requires no investment

but yields a positive return, can be formed if the APT pricing relation is violated in the market. In equilibrium, therefore, if there are no arbitrage opportunities, deviations from the APT pricing relation should not be observed.

- In practice, factor models are widely used as a tool for estimating expected asset returns and their covariance matrix. The reason is that if investors can identify the factors that drive asset returns, they will have much better estimates of the true expected asset returns and the covariance matrix, and hence will be able to form a much better portfolio than otherwise possible.
- Factor model estimation depends crucially on (1) whether the factors are identified (known) and unidentified (latent), and (2) the sample size and the number of assets. Furthermore, factor models can be used not only for explaining asset returns, but also for predicting future returns.
- The simplest case of factor models is where the factors are assumed to be known or observable, so that time-series data are those factors can be used to estimate the model.
- In practice there are three commonly used equity multifactor models where known factors are used: (1) the Fama-French three-factor model, (2) the MSCI Barra fundamental factor model, and (3) the Burmeister-Ibbotson-Roll-Ross macroeconomic factor model. Fundamental factor models use company and industry attributes and market data as descriptors. In a macroeconomic factor model, the inputs to the model are historical stock returns and observable macroeconomic variables.
- An argument for the use of latent factors is that the observed factors may be measured with errors or have been already anticipated by investors. Without imposing what the factors are from likely incorrect beliefs, asset managers can statistically estimate the factors based on the factor model and data.
- Two important extensions of the static factor model used in practice are (1) dynamic fac-

tor models, which allow the factors to evolve over time according to a vector autoregression, and (2) allowance for a large number of factors. This second factor model provides a large dimension reduction that transforms the hundreds of variables into a few, which can be estimated by principal components analysis.

- Principal components analysis is a simple statistical approach that can be applied to estimate a factor model easily and effectively.

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: In investment management, multifactor risk modeling is the most common application of financial modeling. Multifactor risk models, or simply factor models, are linear regressions over a number of variables called factors. Factors can be exogenous variables or abstract variables formed by portfolios. Exogenous factors (or known factors) can be identified from traditional fundamental analysis or economic theory from macroeconomic factors. Abstract factors, also called unidentified or latent factors, can be determined with factor analysis or principal component analysis. Principal component analysis identifies the largest eigenvalues of the variance-covariance matrix or the correlation matrix. The largest eigenvalues correspond to eigenvectors that identify the entire market and sectors that correspond to industry classification. Factor analysis can be used to identify the structure of the latent factors.

Principal component analysis (PCA) and factor analysis are statistical tools that allow a modeler to (1) reduce the number of variables in a model (i.e., to reduce the dimensionality), and (2) identify if there is structure in the relationships between variables (i.e., to classify variables). In this entry, we explain PCA and factor analysis. We illustrate and compare both techniques using a sample of stocks. Because of its use in the estimation of factor models, we begin with a brief discussion of factor models.

FACTOR MODELS

Factor models are statistical models that try to explain complex phenomena through a small number of basic causes or factors. Factor models serve two main purposes: (1) They reduce the dimensionality of models to make estimation possible; and/or (2) they find the true causes that drive data. Factor models were introduced by Charles Spearman (1904), a leading psychologist who developed many concepts of modern psychometrics.

Spearman was particularly interested in understanding how to measure human intellectual abilities. In his endeavor to do so, he developed the first factor model, known as the Spearman model, a model that explains intellectual abilities through one common factor, the famous “general intelligence” g factor, plus another factor s , which is specific to each distinct ability. Spearman was persuaded that the factor g had an overwhelming importance. That is, he thought that any mental ability can be explained quantitatively through a common intelligence factor. According to this theory, outstanding achievements of, say, a painter, a novelist, and a scientist can all be ascribed to a common general intelligence factor plus a small contribution from specific factors.

Some 30 years later, Louis Leon Thurstone (1938) developed the first true multifactor model of intelligence. Thurstone was among the first to propose and demonstrate that there are numerous ways in which a person can be intelligent. Thurstone’s multiple-factors theory identified seven primary mental abilities.

One might question whether factors are only statistical artifacts or if they actually correspond to any reality. In the modern operational interpretation of science, a classification or a factor is “real” if we can make useful predictions using that classification. For example, if the Spearman theory is correct, we can predict that a highly intelligent person can obtain outstanding results in any field. Thus, a novelist could have obtained outstanding results in science. However, if many distinct mental factors are needed, people might be able to achieve great results in some field but be unable to excel in others.

In the early applications of factor models to psychometrics, the statistical model was essentially a conditional multivariate distribution. The raw data were large samples of psychometric tests. The objective was to explain these tests as probability distributions conditional on the value of one or more factors. In this way, one can make predictions of, for example, the

future success of young individuals in different activities.

In finance, factor models are typically applied to time series. The objective is to explain the behavior of a large number of stochastic processes, typically price, returns, or rate processes, in terms of a small number of factors. These factors are themselves stochastic processes. In order to simplify both modeling and estimation, most factor models employed in financial econometrics are static models. This means that time series are assumed to be sequences of temporally independent and identically distributed (IID) random variables so that the series can be thought of as independent samples extracted from one common distribution.

In financial econometrics, factor models are needed not only to explain data but to make estimation feasible. Given the large number of stocks presently available—in excess of 15,000—the estimation of correlations cannot be performed without simplifications. Widely used ensembles such as the S&P 500 or the MSCI Europe include hundreds of stocks and therefore hundreds of thousands of individual correlations. Available samples are insufficient to estimate this large number of correlations. Hence factor models are able to explain all pairwise correlations in terms of a much smaller number of correlations between factors.

Linear Factor Models Equations

Linear factor models are regression models of the following type:

$$X_i = \alpha_i + \sum_{j=1}^K \beta_{ij} f_j + \varepsilon_i$$

where

X_i = a set of N random variables

f_j = a set of K common factors

ε_i = the noise terms associated with each variable X_i

The β_{ij} 's are called the *factor loadings* or factor sensitivities; they express the influence of the j -th factor on the i -th variable.

In this formulation, factor models are essentially *static models*, where the variables and the factors are random variables without any explicit dependence on time. It is possible to add a *dynamic* to both the variables and the factors, but that is beyond the scope of our basic introduction in this entry.

As mentioned above, one of the key objectives of factor models is to reduce the dimensionality of the covariance matrix so that the covariances between the variables X_i are determined only by the covariances between factors. Suppose that the noise terms are mutually uncorrelated, so that

$$E(\varepsilon_i \varepsilon_j) = \begin{cases} 0, & i \neq j \\ \sigma_i^2, & i = j \end{cases}$$

and that the noise terms are uncorrelated with the factors, that is, $E(\varepsilon_i f_j) = 0, \forall i, j$. Suppose also that both factors and noise terms have a zero mean, so that $E(X_i) = \alpha_i$. Factor models that respect the above constraints are called strict factor models.

Let's compute the covariances of a strict factor model:

$$\begin{aligned} & E((X_i - \alpha_i)(X_j - \alpha_j)) \\ &= E\left(\left(\sum_{s=1}^K \beta_{is} f_s + \varepsilon_i\right)\left(\sum_{t=1}^K \beta_{jt} f_t + \varepsilon_j\right)\right) \\ &= E\left(\left(\sum_{s=1}^K \beta_{is} f_s\right)\left(\sum_{t=1}^K \beta_{jt} f_t\right)\right) + E\left(\left(\sum_{s=1}^K \beta_{is} f_s\right)(\varepsilon_j)\right) \\ &\quad + E\left((\varepsilon_i) \sum_{t=1}^K \beta_{jt} f_t\right) + E(\varepsilon_i \varepsilon_j) \\ &= \sum_{s,t} \beta_{is} E(f_s f_t) \beta_{jt} + E(\varepsilon_i \varepsilon_j) \end{aligned}$$

From this expression we can see that the variances and covariances between the variables X_i depend only on the covariances between the factors and the variances of the noise term.

We can express the above compactly in matrix form. Let's write a factor model in matrix form

as follows:

$$\mathbf{X} = \boldsymbol{\alpha} + \boldsymbol{\beta} \mathbf{f} + \boldsymbol{\varepsilon}$$

where

$\mathbf{X} = (X_1, \dots, X_N)'$ = the N -vector of variables

$\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_N)'$ = the N -vector of means

$\boldsymbol{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_N)'$ = the N -vector of idiosyncratic noise terms

$\mathbf{f} = (f_1, \dots, f_K)'$ = the K -vector of factors

$$\boldsymbol{\beta} = \begin{bmatrix} \beta_{11} & \cdots & \beta_{1K} \\ \vdots & \ddots & \vdots \\ \beta_{N1} & \cdots & \beta_{NK} \end{bmatrix}$$

= the $N \times K$ matrix of factor loadings.

Let's define the following:

$\boldsymbol{\Sigma}$ = the $N \times N$ variance-covariance matrix of the variables \mathbf{X}

$\boldsymbol{\Omega}$ = the $K \times K$ variance-covariance matrix of the factors

$\boldsymbol{\Psi}$ = $N \times N$ variance-covariance matrix of the error terms $\boldsymbol{\varepsilon}$

If we assume that our model is a strict factor model, the matrix $\boldsymbol{\Psi}$ will be a diagonal matrix with the noise variances on the diagonal, that is,

$$\boldsymbol{\Psi} = \begin{pmatrix} \psi_1^2 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \psi_N^2 \end{pmatrix}$$

Under the above assumptions, we can express the variance-covariance matrix of the variables in the following way:

$$\boldsymbol{\Sigma} = \boldsymbol{\beta} \boldsymbol{\Omega} \boldsymbol{\beta}' + \boldsymbol{\Psi}$$

In practice, the assumption of a strict factor model might be too restrictive. In applied work, factor models will often be approximate factor models. (See, for example, Bai, 2003.) Approximate factor models allow idiosyncratic terms

to be weakly correlated among themselves and with the factors.

As many different factor models have been proposed for explaining stock returns, an important question is whether a factor model is fully determined by the observed time series. In a strict factor model, factors are determined up to a nonsingular linear transformation. In fact, the above matrix notation makes it clear that the factors, which are hidden, nonobservable variables, are not fully determined by the above factor model. That is, an estimation procedure cannot univocally determine the hidden factors and the factor loadings from the observable variables \mathbf{X} . In fact, suppose that we multiply the factors by any nonsingular matrix \mathbf{R} . We obtain other factors

$$\mathbf{g} = \mathbf{R}\mathbf{f}$$

with a covariance matrix

$$\mathbf{\Omega}_g = \mathbf{R}\mathbf{\Omega}\mathbf{R}^{-1}$$

and we can write a new factor model:

$$\begin{aligned}\mathbf{X} &= \boldsymbol{\alpha} + \boldsymbol{\beta}\mathbf{f} + \boldsymbol{\varepsilon} = \boldsymbol{\alpha} + \boldsymbol{\beta}\mathbf{R}^{-1}\mathbf{R}\mathbf{f} \\ &+ \boldsymbol{\varepsilon} = \boldsymbol{\alpha} + \boldsymbol{\beta}_g\mathbf{g} + \boldsymbol{\varepsilon}\end{aligned}$$

In order to solve this indeterminacy, we can always choose the matrix \mathbf{R} so that the factors \mathbf{g} are a set of orthonormal variables, that is, uncorrelated variables (the orthogonality condition) with unit variance (the normality condition). In order to make the model uniquely identifiable, we can stipulate that factors must be a set of orthonormal variables and that, in addition, the matrix of factor loadings is diagonal. Under this additional assumption, a strict factor model is called a *normal factor model*. Note explicitly that under this assumption, factors are simply a set of standardized independent variables. The model is still undetermined under rotation, that is multiplication by any nonsingular matrix such that $\mathbf{R}\mathbf{R}' = \mathbf{I}$.

In summary, a set of variables has a normal factor representation if it is represented by the following factor model:

$$\mathbf{X} = \boldsymbol{\alpha} + \boldsymbol{\beta}\mathbf{f} + \boldsymbol{\varepsilon}$$

where factors are orthonormal variables and noise terms are such that the covariance matrix can be represented as follows:

$$\Sigma = \boldsymbol{\beta}\boldsymbol{\beta}' + \Psi$$

where $\boldsymbol{\beta}$ is the diagonal matrix of factor loadings and Ψ is a diagonal matrix.

How can we explain the variety of factor models proposed given that a strict factor model could be uniquely identified up to a factor linear transformation? As mentioned, the assumptions underlying strict factor models are often too restrictive and approximate factor models have to be adopted. Approximate factor models are uniquely identifiable only in the limit of an infinite number of series. The level of approximation is implicit in practical models of returns.

Types of Factors and Their Estimation

In financial econometrics, the factors used in factor models can belong to three different categories: macroeconomic factors, fundamental factors, and statistical factors. The first two are factor models that deal with known factors and will not be discussed here.

Note that factors defined through statistical analysis are linear combinations of the variables. That is, if the variables are asset returns, factors are portfolios of assets. They are hidden variables insofar as one does not know the weights of the linear combinations. However, once the estimation process is completed, statistical factors are always linear combinations of variables. If data have a strict factor structure, we can always construct linear combinations of the series (e.g., portfolios of returns) that are perfectly correlated with a set of factors. Often they can be given important economic interpretations. In the following sections we describe the theory and estimation methods of principal components analysis and factor analysis.

PRINCIPAL COMPONENTS ANALYSIS

Principal components analysis (PCA) was introduced by Harold Hotelling (1933). Hotelling proposed PCA as a way to determine factors with statistical learning techniques when factors are not exogenously given. Given a variance-covariance matrix, one can determine factors using the technique of PCA.

PCA implements a dimensionality reduction of a set of observations. The concept of PCA is the following. Consider a set of n stationary time series X_i , for example the 500 series of returns of the S&P 500. Consider next a linear combination of these series, that is, a portfolio of securities. Each portfolio P is identified by an n -vector of weights ω_P and is characterized by a variance σ_P^2 . In general, the variance σ_P^2 depends on the portfolio's weights ω_P . Lastly, consider a normalized portfolio, which has the largest possible variance. In this context, a normalized portfolio is a portfolio such that the squares of the weights sum to one.

If we assume that returns are IID sequences, jointly normally distributed with variance-covariance matrix σ , a lengthy direct calculation demonstrates that each portfolio's return will be normally distributed with variance

$$\sigma_P^2 = \omega_P^T \sigma \omega_P$$

The normalized portfolio of maximum variance can therefore be determined in the following way:

$$\text{Maximize } \omega_P^T \sigma \omega_P$$

subject to the normalization condition

$$\omega_P^T \omega_P = 1$$

where the product is a scalar product. It can be demonstrated that the solution of this problem is the eigenvector ω_1 corresponding to the largest eigenvalue λ_1 of the variance-covariance matrix σ . As σ is a variance-covariance matrix, the eigenvalues are all real.

Consider next the set of all normalized portfolios orthogonal to ω_1 , that is, portfolios com-

pletely uncorrelated with ω_1 . These portfolios are identified by the following relationship:

$$\omega_1^T \omega_P = \omega_P^T \omega_1 = 0$$

We can repeat the previous reasoning. Among this set, the portfolio of maximum variance is given by the eigenvector ω_2 corresponding to the second largest eigenvalue λ_2 of the variance-covariance matrix σ . If there are n distinct eigenvalues, we can repeat this process n times. In this way, we determine the n portfolios P_i of maximum variance. The weights of these portfolios are the orthonormal eigenvectors of the variance-covariance matrix σ . Note that each portfolio is a time series that is a linear combination of the original time series X_i . The coefficients are the portfolios' weights.

These portfolios of maximum variance are all mutually uncorrelated. It can be demonstrated that we can recover all the original return time series as linear combinations of these portfolios:

$$X_j = \sum_{i=1}^n \alpha_{j,i} P_i$$

Thus far we have succeeded in replacing the original n correlated time series X_j with n uncorrelated time series P_i with the additional insight that each X_j is a linear combination of the P_i . Suppose now that only p of the portfolios P_i have a significant variance, while the remaining $n - p$ have very small variances. We can then implement a dimensionality reduction by choosing only those portfolios whose variance is significantly different from zero. Let's call these portfolios factors F .

It is clear that we can approximately represent each series X_i as a linear combination of the factors plus a small uncorrelated noise. In fact we can write

$$X_j = \sum_{i=1}^p \alpha_{j,i} F_i + \sum_{i=p+1}^n \alpha_{j,i} P_i = \sum_{i=1}^p \alpha_{j,i} F_i + \varepsilon_j$$

where the last term is a noise term. Therefore to implement PCA one computes the eigenvalues and the eigenvectors of the variance-covariance matrix and chooses the eigenvalues

significantly different from zero. The corresponding eigenvectors are the weights of portfolios that form the factors. Criteria of choice are somewhat arbitrary.

Suppose, however, that there is a strict factor structure, which means that returns follow a strict factor model as defined earlier in this entry:

$$r = a + \beta f + \varepsilon$$

The matrix β can be obtained diagonalizing the variance-covariance matrix. In general, the structure of factors will not be strict and one will try to find an approximation by choosing only the largest eigenvalues.

Note that PCA works either on the variance-covariance matrix or on the correlation matrix. The technique is the same but results are generally different. PCA applied to the variance-covariance matrix is sensitive to the units of measurement, which determine variances and covariances. This observation does not apply to returns, which are dimensionless quantities. However, if PCA is applied to prices and not to returns, the currency in which prices are expressed matters; one obtains different results in different currencies. In these cases, it might be preferable to work with the correlation matrix.

We have described PCA in the case of time series, which is the relevant case in econometrics. However, PCA is a generalized dimensionality reduction technique applicable to any set of multidimensional observations. It admits a simple geometrical interpretation, which can be easily visualized in the three-dimensional case. Suppose a cloud of points in the three-dimensional Euclidean space is given. PCA finds the planes that cut the cloud of points in such a way as to obtain the maximum variance.

Illustration of Principal Components Analysis

Let's now show how PCA is performed. To do so, we used monthly observations for the following 10 stocks: Campbell Soup, General

Dynamics, Sun Microsystems, Hilton, Martin Marietta, Coca-Cola, Northrop Grumman, Mercury Interactive, Amazon.com, and United Technologies for the period from December 2000 to November 2005. Figure 1 shows the graphics of the 10 return processes.

As explained earlier, performing PCA is equivalent to determining the eigenvalues and eigenvectors of the covariance matrix or of the correlation matrix. The two matrices yield different results. We perform both exercises, estimating the principal components using separately the covariance and the correlation matrices of the return processes. We estimate the covariance with the empirical covariance matrix. Recall that the empirical covariance σ_{ij} between variables (X_i, X_j) is defined as follows:

$$\hat{\sigma}_{ij} = \frac{1}{T} \sum_{t=1}^T (X_i(t) - \bar{X}_i)(X_j(t) - \bar{X}_j)$$

$$\bar{X}_i = \frac{1}{T} \sum_{t=1}^T X_i(t), \quad \bar{X}_j = \frac{1}{T} \sum_{t=1}^T X_j(t)$$

Table 1 shows the covariance matrix.

Normalizing the covariance matrix with the standard deviations, we obtain the correlation matrix. Table 2 shows the correlation matrix. Note that the diagonal elements of the correlation matrix are all equal to one. In addition, a number of entries in the covariance matrix are close to zero. Normalization by the product of standard deviations makes the same elements larger.

Let's now proceed to perform PCA using the covariance matrix. We have to compute the eigenvalues and the eigenvectors of the covariance matrix. Table 3 shows the eigenvectors (panel A) and the eigenvalues (panel B) of the covariance matrix.

Each column of panel A of Table 3 represents an eigenvector. The corresponding eigenvalue is shown in panel B. Eigenvalues are listed in descending order; the corresponding eigenvectors go from left to right in the matrix of eigenvectors. Thus the leftmost eigenvector corresponds

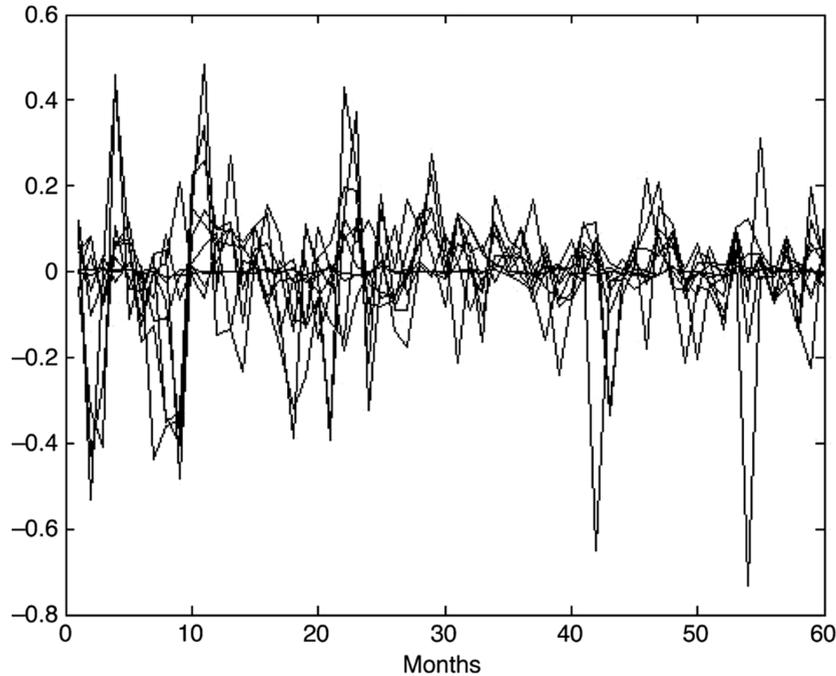

Figure 1 Graphics of the 10 Stock Return Processes

to the largest eigenvalue. Eigenvectors are not uniquely determined. In fact, multiplying any eigenvector for a real constant yields another eigenvector. The eigenvectors in Table 3 are normalized in the sense that the sum of the squares of each component is equal to 1. It can be easily checked that the sum of the squares of the elements in each column is equal to 1. This still leaves an indeterminacy, as we can change the

sign of the eigenvector without affecting this normalization.

As explained earlier, if we form portfolios whose weights are the eigenvectors, we can form 10 portfolios that are orthogonal (i.e., uncorrelated). These orthogonal portfolios are called *principal components*. The variance of each principal component will be equal to the corresponding eigenvector. Thus the first principal

component (i.e., the portfolio corresponding to the first eigenvalue), will have the maximum possible variance and the last principal component (i.e., the portfolio corresponding to the last eigenvalue) will have the smallest variance. Figure 2 shows the graphics of the principal components of maximum and minimum variance.

The 10 principal components thus obtained are linear combinations of the original series, $\mathbf{X} = (X_1, \dots, X_N)'$ that is, they are obtained by multiplying \mathbf{X} by the matrix of the eigenvectors. If the eigenvalues and the corresponding eigenvectors are all distinct, as it is the case in our illustration, we can apply the inverse

transformation and recover the X as linear combinations of the principal components.

PCA is interesting if, in using only a small number of principal components, we nevertheless obtain a good approximation. That is, we use PCA to determine principal components but we use only those principal components that have a large variance as factors of a factor model. Stated otherwise, we regress the original series X onto a small number of principal components. In this way, PCA implements a dimensionality reduction as it allows one to retain only a small number of components. By choosing as factors the components with the largest variance, we can explain a large portion of the total variance of X .

Table 4 shows the total variance explained by a growing number of components. Thus the first component explains 55.2784% of the total variance, the first two components explain 66.8507% of the total variance, and so on. Obviously 10 components explain 100% of the

total variance. The second, third, and fourth columns of Table 5 show the residuals of the Sun Microsystems return process with 1, 5, and all 10 components, respectively. There is a large gain from 1 to 5, while the gain from 5 to all 10 components is marginal.

Table 4 Percentage of the Total Variance Explained by a Growing Number of Components Based on the Covariance Matrix

Principal Component	Percentage of Total Variance Explained
1	55.2784%
2	66.8508
3	76.4425
4	84.1345
5	91.2774
6	95.1818
7	97.9355
8	99.8982
9	99.9637
10	100.0000

9	0.3143
10	0.2258

We can repeat the same exercise for the correlation matrix. Table 6 shows the eigenvectors (panel A) and the eigenvalues (panel B) of the correlation matrix. Eigenvectors are normalized as in the case of the covariance matrix.

Table 7 shows the total variance explained by a growing number of components. Thus the first component explains 30.6522% of the total variance, the first two components explain

Table 7 Percentage of the Total Variance Explained by a Growing Number of Components Using the Correlation Matrix

Principal Component	Percentage of Total Variance Explained
1	30.6522%
2	45.2509
3	57.1734
4	67.0935
5	75.7044
6	82.6998
7	88.8901
8	94.5987
9	97.7417
10	100.0000

45.2509% of the total variance, and so on. Obviously 10 components explain 100% of the total variance. The increase in explanatory power with the number of components is slower than in the case of the covariance matrix.

The proportion of the total variance explained grows more slowly in the correlation case than in the covariance case. Figure 3 shows the graphics of the portfolios of maximum and minimum variance. The ratio between the two portfolios is smaller in this case than in the case of the covariance.

The last three columns of Table 6 show the residuals of the Sun Microsystems return process with 1, 5, and all components based on the correlation matrix. Residuals are progressively reduced, but at a lower rate than with the covariance matrix.

PCA and Factor Analysis with Stable Distributions

In the previous sections we discussed PCA and factor analysis without making any explicit

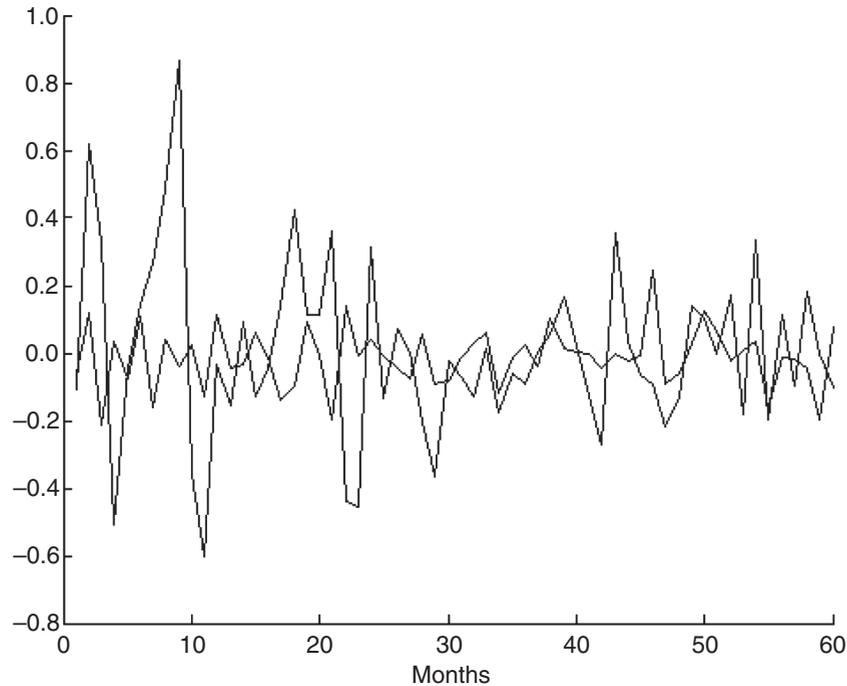

Figure 3 Graphic of the Portfolios of Maximum and Minimum Variance Based on the Correlation Matrix

reference to the distributional properties of the variables. These statistical tools can be applied provided that all variances and covariances exist. Therefore applying them does not require, per se, that distributions are normal, but only that they have finite variances and covariances. Variances and covariances are not robust but are sensitive to outliers. Robust equivalents of variances and covariances exist. In order to make PCA and factor analysis insensitive to outliers, one could use robust versions of variances and covariances and apply PCA and factor analysis to these robust estimates.

In many cases, however, distributions might exhibit fat tails and infinite variances. In this case, large values cannot be trimmed but must be taken into proper consideration. However, if variances and covariances are not finite, the least squares methods used to estimate factor loadings cannot be applied. In addition, the concept of PCA and factor analysis as illustrated in the previous sections cannot be

applied. In fact, if distributions have infinite variances, it does not make sense to determine the portfolio of maximum variance as all portfolios will have infinite variance and it will be impossible, in general, to determine an ordering based on the size of variance.

Both PCA and factor analysis as well as the estimation of factor models with infinite-variance error terms are at the forefront of econometric research.

FACTOR ANALYSIS

Thus far, we have seen how factors can be determined using principal components analysis. We retained as factors those principal components with the largest variance. In this section, we consider an alternative technique for determining factors: *factor analysis* (FA). Suppose we are given T independent samples of a random vector $\mathbf{X} = (X_1, \dots, X_N)'$. In the most common cases in financial econometrics, we will be given

T samples of a multivariate time series. However, factor analysis can be applied to samples extracted from a generic multivariate distribution. To fix these ideas, suppose we are given N time series of stock returns at T moments, as in the case of PCA.

Assuming that the data are described by a strict factor model with K factors, the objective of factor analysis (FA) consists of determining a model of the type

$$\mathbf{X} = \boldsymbol{\alpha} + \boldsymbol{\beta}\mathbf{f} + \boldsymbol{\varepsilon}$$

with covariance matrix

$$\boldsymbol{\Sigma} = \boldsymbol{\beta}\boldsymbol{\beta}' + \boldsymbol{\Psi}$$

The estimation procedure is performed in two steps. In the first step, we estimate the covariance matrix and the factor loadings. In the second step, we estimate factors using the covariance matrix and the factor loadings.

If we assume that the variables are jointly normally distributed and temporally IID, we can estimate the covariance matrix with maximum likelihood methods. Estimation of factor models with maximum likelihood methods is not immediate because factors are not observable. Iterative methods such as the *expectation maximization* (EM) algorithm are generally used.

After estimating the matrices $\boldsymbol{\beta}$ and $\boldsymbol{\Psi}$ factors can be estimated as linear regressions. In fact, assuming that factors are zero means (an assumption that can always be made), we can write the factor model as

$$\mathbf{X} - \boldsymbol{\alpha} = \boldsymbol{\beta}\mathbf{f} + \boldsymbol{\varepsilon}$$

which shows that, at any given time, factors can be estimated as the regression coefficients of the regression of $(\mathbf{X} - \boldsymbol{\alpha})$ onto $\boldsymbol{\beta}$. Using the standard formulas of regression analysis, we can now write factors, at any given time, as follows:

$$\hat{\mathbf{f}}_t = \left(\hat{\boldsymbol{\beta}}' \hat{\boldsymbol{\Psi}}^{-1} \hat{\boldsymbol{\beta}} \right)^{-1} \hat{\boldsymbol{\beta}}' \hat{\boldsymbol{\Psi}}^{-1} (\mathbf{X}_t - \hat{\boldsymbol{\alpha}})$$

The estimation approach based on maximum likelihood estimates implies that the number of factors is known. In order to determine the number of factors, a heuristic procedure consists of iteratively estimating models with a

growing number of factors. The correct number of factors is determined when estimates of q factors stabilize and cannot be rejected on the basis of p probabilities. A theoretical method for determining the number of factors was proposed by Bai and Ng (2002).

The factor loadings matrix can also be estimated with ordinary least squares (OLS) methods. The OLS estimator of the factor loadings coincides with the principal component estimator of factor loadings. However, in a strict factor model, OLS estimates of the factor loadings are inconsistent when the number of time points goes to infinity but the number of series remains finite, unless we assume that the idiosyncratic noise terms all have the same variance.

The OLS estimators, however, remain consistent if we allow both the number of processes and the time to go to infinity. Under this assumption, as explained by Bai (2003), we can also use OLS estimators for approximate factor models.

In a number of applications, we might want to enforce the condition $\alpha = 0$. This condition is the condition of asset of arbitrage. OLS estimates of factor models with this additional condition are an instance of constrained OLS methods.

An Illustration of Factor Analysis

Let's now show how factor analysis is performed. To do so, we will use the same 10 stocks and return data for December 2000 to November 2005 that we used to illustrate principal components analysis.

As just described, to perform factor analysis, we need estimate only the factor loadings and the idiosyncratic variances of noise terms. We assume that the model has three factors. Table 8 shows the factor loadings. Each row represents the loadings of the three factors corresponding to each stock. The last column of the table shows the idiosyncratic variances.

The idiosyncratic variances are numbers between 0 and 1, where 0 means that the variance

Table 8 A Factor Loadings and Idiosyncratic Variances

is completely explained by common factors and 1 that common factors fail to explain variance.

The p -value turns out to be 0.6808 and therefore fails to reject the null of three factors. Estimating the model with 1 and 2 factors we obtain much lower p -values while we run into numerical difficulties with 4 or more factors. We can therefore accept the null of three factors. Figure 4 shows the graphics of the three factors.

PCA AND FACTOR ANALYSIS COMPARED

The two illustrations of PCA and FA are relative to the same data and will help clarify the differences between the two methods. Let's first observe that PCA does not imply, per se, any specific restriction on the process. Given a nonsingular covariance matrix, we can always

**Figure 4** Graph of the three factors

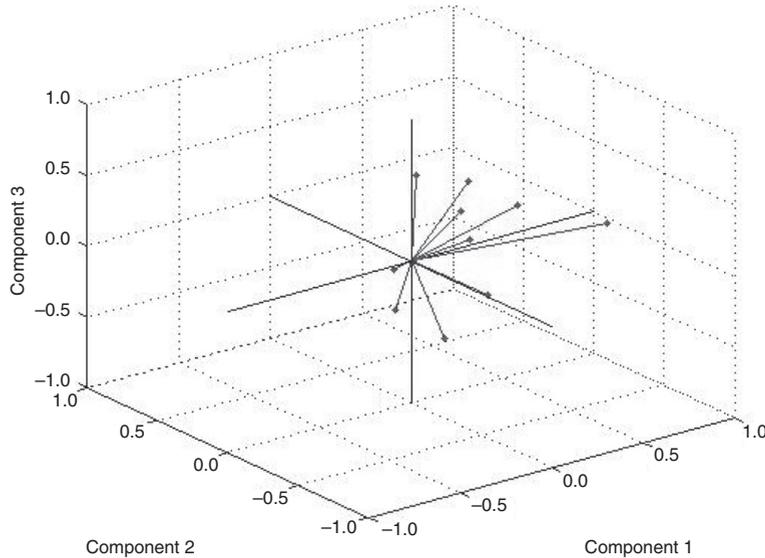

Figure 5 Graphical Representation of Factor Loadings

perform PCA as an exact linear transformation of the series. When we consider a smaller number of principal components, we perform an approximation that has to be empirically justified. For example, in our PCA illustration, the first three components explain 76% of the total variance (based on the covariance matrix; see Table 4).

Factor analysis, on the other hand, assumes that the data have a strict factor structure in the sense that the covariance matrix of the data can be represented as a function of the covariances between factors plus idiosyncratic variances. This assumption has to be verified, otherwise the estimation process might yield incorrect results.

In other words, PCA tends to be a dimensionality reduction technique that can be applied to any multivariate distribution and that yields incremental results. This means that there is a trade-off between the gain in estimation from dimensionality reduction and the percentage of variance explained. Consider that PCA is not an estimation procedure: It is an exact linear transformation of a time series. Estimation comes into play when a reduced number of princi-

pal components is chosen and each variable is regressed onto these principal components. At this point, a reduced number of principal components yields a simplified regression, which results in a more robust estimation of the covariance matrix of the original series though only a fraction of the variance is explained.

Factor analysis, on the other hand, tends to reveal the exact factor structure of the data. That is, FA tends to give an explanation in terms of what factors explain what processes. Factor rotation can be useful both in the case of PCA and FA. Consider FA. In our illustration, to make the factor model identifiable, we applied the restriction that factors are orthonormal variables. This restriction, however, might result in a matrix of factor loadings that is difficult to interpret.

For example, if we look at the loading matrix in Table 8, there is no easily recognizable structure, in the sense that the time series is influenced by all factors. Figure 5 shows graphically the relationship of the time series to the factors. In this graphic, each of the 10 time series is represented by its three loadings.

We can try to obtain a better representation through factor rotation. The objective is to

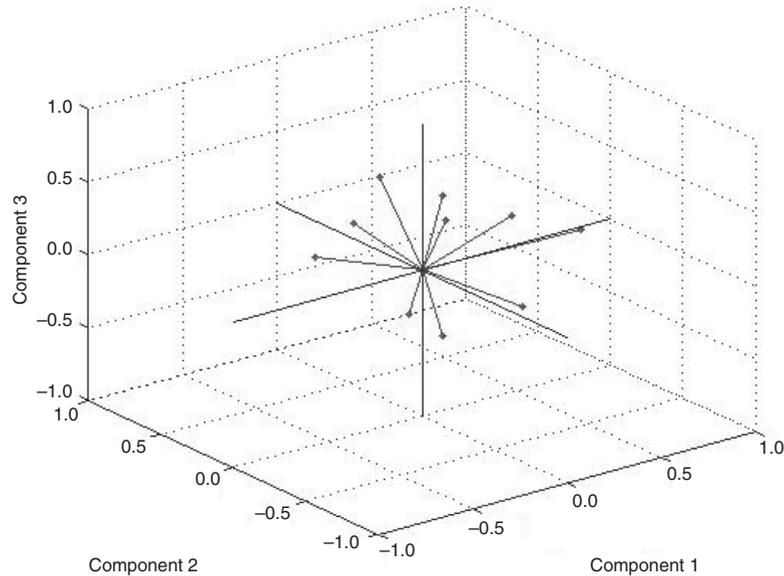

Figure 6 Relationship of Time Series to the Factors after Rotation

create factors such that each series has only one large loading and thus is associated primarily with one factor. Several procedures have been proposed for doing so. For example, if we rotate factors using the “promax” method, we obtain factors that are no longer orthogonal but that often have a better explanatory power. Figure 6 shows graphically the relationship of time series to the factors after rotation. The association of the series to a factor is more evident. This fact can be seen from the matrix of new factor loadings in Table 9, which shows how nearly each stock has one large loading.

KEY POINTS

- Principal component analysis (PCA) and factor analysis are statistical tools used in financial modeling to reduce the number of variables in a model (i.e., to reduce the dimensionality) and to identify a structure in the relationships between variables.
- Factor models seek to explain complex phenomena via a small number of basic causes or factors. In finance these models are typically applied to time series.
- The objective of a factor model in finance is to explain the behavior of a large number of stochastic processes typically price, returns, or rate processes in terms of a small number of factors (which themselves are stochastic processes). In financial modeling, factor models are needed not only to explain data but to make estimation feasible.
- Linear factor models are regression models. The coefficients are referred to as factor loadings or factor sensitivities, and they represent the influence of a factor on some variable.
- Principal components analysis is a tool to determine factors with statistical learning

techniques when factors are not exogenously given. PCA implements a dimensionality reduction of a set of observations.

- Performing PCA is equivalent to determining the eigenvalues and eigenvectors of the covariance matrix or of the correlation matrix.
- Factor analysis is an alternative technique for determining factors. The estimation procedure is performed in two steps: (1) estimate the covariance matrix and the factor loadings, and (2) estimate factors using the covariance matrix and the factor loadings.
- The covariance matrix can be estimated with maximum likelihood methods, assuming that the variables are jointly normally distributed and temporally independently and identically distributed. The estimation of models with maximum likelihood methods is not immediate because factors are not observable, and consequently iterative methods such as

the expectation maximization (EM) algorithm are generally used.

CENK URAL, PhD
Vice President, Barclays

Abstract: Multifactor risk models seek to estimate and characterize the risk of a portfolio, either in absolute value or when compared against a benchmark. Risk is typically decomposed into a systematic and an idiosyncratic component. Systematic risk captures the exposures the portfolio has to broad risk factors. For equity portfolios these are typically countries, industries, fundamental (e.g., size), or technical (e.g., momentum). The portfolio systematic risk depends on its exposure to these risk factors, the volatility of the factors, and how they correlate with each other. Idiosyncratic risk captures the uncertainty associated with news affecting only individual issuers in the portfolio. This risk can be diversified by decreasing the importance of individual issuers in the portfolio. Intuitive multifactor risk models can provide relevant information regarding the major sources of risk in the portfolio. This information can be used to understand the important imbalances of the portfolio and guide the portfolio manager in constructing or rebalancing the portfolio. It can also be used in interpreting results from return attribution or scenario analysis.

Risk management is an integral part of the portfolio management process. *Risk models* are central to this practice, allowing managers to quantify and analyze the risk embedded in their

portfolios. Risk models provide managers insight into the major sources of risk in a portfolio, helping them to control their exposures and understand the contributions of different

The authors would like to thank Andy Sparks, Anuj Kumar, and Chris Sturhahn of Barclays for their help and comments.

portfolio components to total risk. They help portfolio managers in their decision-making process by providing answers to important questions such as: How does my small-cap exposure affect portfolio risk? Does my underweight in diversified financials hedge my overweight in banks? Risk models are also widely used in various other areas such as in portfolio construction, performance attribution, and scenario analysis.

In this entry, we discuss the structure of multifactor equity risk models, types of factors used in these models, and describe certain estimation techniques. We also illustrate the use of equity risk factor models in various applications, namely the analysis of portfolio risk, portfolio construction, scenario analysis, and performance attribution.

Throughout this entry, we will be using the Barclays Global Risk Model¹ for illustration purposes. For completeness, we also refer to other approaches one can take to construct such a model.

MOTIVATION

In this section, we discuss the motivation behind the multifactor equity risk models. Let's assume that a portfolio manager wants to estimate and analyze the volatility of a large portfolio of stocks. A straightforward idea would be to compute the volatility of the historical returns of the portfolio and use this measure to forecast future volatility. However, this framework does not provide any insight into the relationships between different securities in the portfolio or the major sources of risk. For instance, it does not assist a portfolio manager interested in diversifying her portfolio or constructing a portfolio that has better risk-adjusted performance.

Instead of estimating the portfolio volatility using historical portfolio returns, one could utilize a different strategy. The portfolio return is a function of stock returns and the market weights of these stocks in the portfolio. Us-

ing this, the forecasted volatility of the portfolio (σ_p) can be computed as a function of the weights (w) and the covariance matrix (Σ_s) of stock returns in the portfolio:

$$\sigma_p^2 = w^T \cdot \Sigma_s \cdot w$$

This covariance matrix can be decomposed into individual stock volatilities and the correlations between stock returns. Volatilities measure the riskiness of individual stock returns and correlations represent the relationships between the returns of different stocks. Looking into these correlations and volatilities, the portfolio manager can gain insight into her portfolio, namely the riskiness of different parts of the portfolio or how the portfolio can be diversified. As we outlined above, to estimate the portfolio volatility we need to estimate the correlation between each pair of stocks. Unfortunately, this means that the number of parameters to be estimated grows quadratically with the number of stocks in the portfolio.² For most practical portfolios, the relatively large number of stocks makes it difficult to estimate the relationship between stock returns in a robust way. Moreover, this framework uses the history of individual stock returns to forecast future stock volatility. However, stock characteristics are dynamic and hence using returns from different time periods may not produce good forecasts.³ Finally, the analysis does not provide much insight regarding the broad factors influencing the portfolio. These drawbacks constitute the motivation for the multifactor risk models detailed in this entry.

One of the major goals of multifactor risk models is to describe the return of a portfolio using a smaller set of variables, called factors. These factors should be designed to capture broad (systematic) market fluctuations, but should also be able to capture specific nuances of individual portfolios. For instance, a broad U.S. market factor would capture the general movement in the equity market, but not the varying behavior across industries. If our portfolio is heavily biased toward particular

industries, the broad U.S. market factor may not allow for a good representation of our portfolio's return.

In the context of factor models, the total return of a stock is decomposed into a systematic and an idiosyncratic component. Systematic return is the component of total return due to movements in common risk factors, such as industry or size. On the other hand, idiosyncratic return can be described as the residual component that cannot be explained by the systematic factors. Under these models, the idiosyncratic return is uncorrelated across issuers. Therefore, correlations across securities are driven by their exposures to the systematic risk factors and the correlation between those factors.

The following equation demonstrates the systematic and the idiosyncratic components of total stock return:

$$r_s = L_s \cdot F + \varepsilon_s$$

The systematic return for security s is the product of the loadings of that security (L_s , also called sensitivities) to the systematic risk factors and the returns of these factors (F). The idiosyncratic return is given by ε_s . Under these models, the portfolio volatility can be estimated as

$$\sigma_p^2 = L_p^T \cdot \Sigma_F \cdot L_p + w^T \cdot \Omega \cdot w$$

Models represented by equations of this form are called linear factor models. Here L_p represents the loadings of the portfolio to the risk factors (determined as the weighted average of individual stock loadings), and Σ_F is the covariance matrix of factor returns. w is the vector of security weights in the portfolio, and Ω is the covariance matrix of idiosyncratic stock returns. Due to the uncorrelated nature of these returns, this covariance matrix is diagonal: all elements outside its diagonal are zero. As a result, the idiosyncratic risk of the portfolio is diversified away as the number of securities in the portfolio increases. This is the diversification benefit attained when combining uncorrelated exposures.

For most practical portfolios, the number of factors is significantly smaller than the number of stocks in the portfolio. Therefore, the number of parameters in Σ_F is much smaller than in Σ_S , leading to a generally more robust estimation. Moreover, the factors can be designed in a way that they are relatively more stable than individual stock returns, leading to models with potentially better predictability.

Another important advantage of using linear factor models is the detailed insight they provide into the structure and properties of portfolios. These models characterize stock returns in terms of systematic factors that (can) have intuitive economic interpretations. Linear factor models can provide important insights regarding the major systematic and idiosyncratic sources of risk and return. This analysis can help managers to better understand their portfolios and can guide them through the different tasks they perform, such as rebalancing, hedging, or the tilting of their portfolios. The Barclays Global Risk Model—the model used for illustration throughout this entry—is an example of such a linear factor model.

EQUITY RISK FACTOR MODELS

The design of a linear factor model usually starts with the identification of the major sources of risk embedded in the portfolios of interest. For an equity portfolio manager who invests in various markets across the globe, the major sources of risk are typically country, industry membership, and other fundamental or technical exposures such as size, value, and momentum. The relative significance of these components varies across different regions. For instance, for regional equity risk models in developed markets, industry factors tend to be more important than country factors, although in periods of financial distress country factors become more significant. On the other hand, for emerging markets models the country factor is still considered to be the most important

source of risk. For regional models, the relative significance of industry factors depends on the level of financial integration across different local markets in that region. The importance of these factors is also time-varying, depending on the particular time period of the analysis. For instance, country risk used to be a large component of total risk for European equity portfolios. However, country factors have been generally losing their significance in this context due to financial integration in the region as a result of the European Union and a common currency, the euro. This is particularly true for larger European countries. Similarly, the relative importance of industry factors is higher over the course of certain industry-led crises, such as the dot-com bubble burst (2000–2002) and the 2007–2009 banking and credit crisis. As we will see, the relative importance of different risk factors varies also with the particular design and the estimation process chosen to calibrate the model.

A typical global or regional equity risk model has the following structure:

$$r_i = \beta_i^{\text{MKT}} \cdot F^{\text{MKT}} + \beta_i^{\text{IND}} \cdot F^{\text{IND}} + \beta_i^{\text{CNT}} \cdot F^{\text{CNT}} + \sum_{j=1}^n \ell_{ij} \cdot F_j^{\text{FT}} + \varepsilon_i$$

where

- r_i = the rate of return for stock i
- F^{MKT} = the market factor
- F^{IND} = the industry factor corresponding to stock i
- F^{CNT} = the country factor corresponding to stock i
- β_i = the exposure (beta) of the stock to the corresponding factor
- F^{FT} = the set of fundamental and technical factors
- ℓ_{ij} = the loading of stock i to factor F_j^{FT}
- ε_i = the residual return for stock i

There are different ways in which these factors can be incorporated into an equity risk model. The choice of a particular model

affects the interpretation of the factors. For instance, consider a model that has only market and industry factors. Industry factors in such a model would represent industry-specific moves net of the market return. On the other hand, if we remove the market factor from the equation, the industry factors now incorporate the overall market effect. Their interpretation would change, with their returns now being close to market value-weighted industry indexes. Country-specific risk models are a special case of the previous representation where the country factor disappears and the market factor is represented by the returns of the countrywide market. Macroeconomic factors are also used in some equity risk models, as discussed later.

The choice of estimation process also influences the interpretation of the factors. As an example, consider a model that has only industry and country factors. These factors can be estimated jointly in one step. In this case, both factors represent their own effect net of the other ones. On the other hand, these factors can be estimated in a multistep process—e.g., industry factors estimated in the first step and then the country factors estimated in the second step, using residual returns from the first step. In this case, the industry factors have an interpretation close to the market value-weighted industry index returns, while the country factors would now represent a residual country average effect, net of industry returns. We discuss this issue in more detail in the following section.

Model Estimation

In terms of the estimation methodology, there are three major types of multi-factor equity risk models: cross-sectional, time series, and statistical. All three of these methodologies are widely used to construct linear factor models in the equity space.⁴ In cross-sectional models, loadings are known and factors are estimated. Examples of loadings used in these models are industry

membership variables and fundamental security characteristics (e.g., the book-to-price ratio). Individual stock returns are regressed against these security-level loadings in every period, delivering estimation of factor returns for that period. The interpretation of these estimated factors is usually intuitive, although dependent on the estimation procedure and on the quality of the loadings. In time-series models, factors are known and loadings are estimated. Examples of factors in these models are financial or macroeconomic variables, such as market returns or industrial production. Time series of individual equity returns are regressed against the factor returns, delivering empirical sensitivities (loadings or betas) of each stock to the risk factors. In these models, factors are constructed and not estimated, therefore, their interpretation is straightforward. In statistical models (e.g., principal component analysis), both factors and loadings are estimated jointly in an iterative fashion. The resulting factors are statistical in nature, not designed to be intuitive. That being said, a small set of the statistical factors can be (and usually are) correlated with broad economic factors, such as the market. Table 1 summarizes some of the characteristics of these models.

An important advantage of cross-sectional models is that the number of parameters to be

estimated is generally significantly smaller as compared to the other two types of models. On the other hand, cross-sectional models require a much larger set of input data (company-specific loadings). Cross-sectional models tend to be relatively more responsive as loadings can adjust faster to changing market conditions. There are also hybrid models, which combine cross-sectional and time-series estimation in an iterative fashion; these models allow the combination of observed and estimated factors. Finally, statistical models require only a history of security returns as input to the process. They tend to work better when economic sources of risk are hard to identify and are primarily used in high-frequency applications.

As we mentioned in the previous section, the estimation process is a major determinant in the interpretation of factors. Estimating all factors jointly in one-step regression allows for a natural decomposition of total variance in stock returns. However it also complicates the interpretation of factors as each factor now represents its own effect net of all other factors. Moreover, multicollinearity problems arise naturally in this set-up, potentially delivering lack of robustness to the estimation procedure and leading to unintuitive factor realizations. This problem can be serious when using factors that are highly correlated.

Table 1 Cross-Sectional, Time-Series, and Statistical Factor Models

Model	Cross-Sectional	Time-Series	Statistical
Input set	Security-specific loadings and returns	Factor and security returns	Security returns
Factors and loadings	Factors are estimated using the known loadings (e.g., industry beta or momentum score)	Factors are known (e.g., market or industrial production) and loadings are estimated (e.g., industry or momentum betas)	Both factors and loadings are estimated
Interpretation	Clean interpretation of loadings; generally intuitive interpretation of factors	Straightforward interpretation of factors	Factors may have no intuitive interpretation
Number of parameters	(No. of factors) × (No. of time periods)	(No. of securities) × (No. of factors)	(No. of securities) × (No. of factors)

An alternative in this case is to use a multistep estimation process where different sets of factors are estimated sequentially, in separate regressions. In the first step, stock returns are used in a regression to estimate a certain set of factors, and then residual returns from this step are used to estimate the second step factors, and so on. The choice of the order of factors in such estimation influences the nature of the factors and their realizations. This choice should be guided by the significance and the desired interpretation of the resulting factors. The first-step factors have the most straightforward interpretation as they are estimated in isolation from all other factors using raw stock returns. For instance, in a country-specific equity risk model where there are industry, fundamental and technical factors, the return series of industry factors would be close to the industry index returns if they are estimated in isolation in the first step. This would not be the case if all industry, fundamental, and technical factors are estimated in the same step.

An important input to the model estimation is the security weights used in the regressions. There is a variety of techniques employed in practice but generally more weight is assigned to less volatile stocks (usually represented by larger companies). This enhances the robustness of the factor estimates as stocks from these companies tend to have relatively more stable return distributions.

Types of Factors

In this section, we analyze in more detail the different types of factors typically used in equity risk models. These can be classified under five major categories: market factors, classification variables, firm characteristics, macroeconomic variables, and statistical factors.

Market Factors

A market factor can be used as an observed factor in a time-series setting (e.g., in the cap-

ital asset pricing model, the market factor is the only systematic factor driving returns). As an example, for a U.S. equity factor model, S&P 500 can be used as a market factor and the loading to this factor—market beta—can be estimated by regressing individual stock returns to the S&P 500. On the other hand, in a cross-sectional setting, the market factor can be estimated by regressing stock returns to their market beta for each time period (this beta can be empirical—estimated via statistical techniques—or set as a dummy loading, usually 1). When incorporated into a cross-sectional regression with other factors, it generally works as an intercept, capturing the broad average return for that period. This changes the interpretation of all other factors to returns relative to that average (e.g., industry factor returns would now represent industry-specific moves net of market).

Classification Variables

Industry and country are the most widely used classification variables in equity risk models. They can be used as observed factors in time-series models via country/industry indexes (e.g., return series of GICS indexes⁵ can be used as observed industry factors). In a cross-sectional setting, these factors are estimated by regressing stock returns to industry/country betas (either estimated or represented as a 0/1 dummy loading). These factors constitute a significant part of total risk for a majority of equity portfolios, especially for portfolios tilted toward specific industries or countries.

Firm Characteristics

Factors that represent firm characteristics can be classified as either fundamental or technical factors. These factors are extensively used in equity risk models; exposures to these factors represent tilts towards major investment themes such as size, value, and momentum. Fundamental factors generally employ a mix of

accounting and market variables (e.g., accounting ratios) and technical factors commonly use return and volume data (e.g., price momentum or average daily volume traded).

In a time-series setting, these factors can be constructed as representative long-short portfolios (e.g., Fama-French factors). As an example, the value factor can be constructed by taking a long position in stocks that have a large book to price ratio and a short position in the stocks that have a small book to price ratio. On the other hand, in a cross-sectional setup, these factors can be estimated by regressing the stock returns to observed firm characteristics. For instance, a book to price factor can be estimated by regressing stock returns to the book to price ratios of the companies. In practice, fundamental and technical factors are generally estimated jointly in a multivariate setting.

A popular technique in the cross-sectional setting is the standardization of the characteristic used as loading such that it has a mean of zero and a standard deviation of one. This implies that the loading to the corresponding factor is expressed in relative terms, making the exposures more comparable across the different fundamental/technical factors. Also, similar characteristics can be combined to form a risk index and then this index can be used to estimate the relevant factor (e.g., different value ratios such as earnings to price and book to price can be combined to construct a value index, which would be the exposure to the value factor). The construction of an index from similar characteristics can help reduce the problem of multicollinearity referred to above. Unfortunately, it can also dilute the signal each characteristic has, potentially reducing its explanatory power. This trade-off should be taken into account while constructing the model. The construction of fundamental factors and their loadings requires careful handling of accounting data. These factors tend to become more significant for portfolios that are hedged with respect to the market or industry exposures.

Macroeconomic Variables

Macroeconomic factors, representing the state of the economy, are generally used as observed factors in time-series models. Widely used examples include interest rates, commodity indexes, and market volatility (e.g., the VIX index). These factors tend to be better suited for models with a long horizon. For short to medium horizons, they tend to be relatively insignificant when included in a model that incorporates other standard factors such as industry. The opposite is not true, suggesting that macro factors are relatively less important for these horizons. This does not mean that the macroeconomic variables are not relevant in explaining stock returns; it means that a large majority of macroeconomic effects can be captured through the industry factors. Moreover, it is difficult to directly estimate stock sensitivities to slow-moving macroeconomic variables. These considerations lead to the relatively infrequent use of macro variables in short to medium horizon risk models.⁶

Statistical Factors

Statistical factors are very different in nature from all the aforementioned factors as they do not have direct economic interpretation. They are estimated using statistical techniques such as principal component analysis where both factors and loadings are estimated jointly in an iterative fashion. Their interpretation can be difficult, yet in certain cases they can be re-mapped to well-known factors. For instance, in a principal component analysis model for the U.S. equity market, the first principal component would represent the U.S. market factor. These models tend to have a relatively high in-sample explanatory power with a small set of factors and the marginal contribution of each factor tends to diminish significantly after the first few factors. Statistical factors can also be used to capture the residual risk in a model with economic factors. These factors tend to work better when there are unidentified sources of risk such as in the case of high-frequency models.

Other Considerations in Factor Models

Various quantitative and qualitative measures can be employed to evaluate the relative performance of different model designs. Generically, better risk models are able to forecast more accurately the risk of different types of portfolios across different economic environments. Moreover, a better model allows for an intuitive analysis of the portfolio risk along the directions used to construct and manage the portfolio. The relative importance of these considerations should frame how we evaluate different models.

A particular model is defined by its estimation framework and the selection of its factors and loadings. Typically, these choices are evaluated jointly, as the contributions of specific components are difficult to measure in practice. Moreover, decisions on one of these components (partially) determine the choice of the others. For instance, if a model uses fundamental firm characteristics as loadings, it also uses estimated factors—more generally, decisions on the nature of the factors determine the nature of the loadings and vice-versa.

Quantitative measures of factor selection include the explanatory power or significance of the factor, predictability of the distribution of the factor, and correlations between factors. On a more qualitative perspective, portfolio managers usually look for models with factors and loadings that have clean and intuitive interpretation, factors that correspond to the way they think about the asset class, and models that reflect their investment characteristics (e.g., short vs. long horizon, local vs. global investors).

Idiosyncratic Risk

Once all systematic factors and loadings are estimated, the residual return can be computed as the component of total stock return that cannot be explained by the systematic factors. Idiosyncratic return—also called residual, nonsystematic, or name-specific return—can

be a significant component of total return for individual stocks, but tends to become smaller for portfolios of stocks as the number of stocks increases and concentration decreases (the aforementioned diversification effect). The major input to the computation of idiosyncratic risk is the set of historical idiosyncratic returns of the stock. Because the nature of the company may change fast, a good idiosyncratic risk model should use only recent and relevant idiosyncratic returns. Moreover, recent research suggests that there are other conditional variables that may help improve the accuracy of idiosyncratic risk estimates. For instance, there is substantial evidence that the market value of a company is highly correlated with its idiosyncratic risk, where larger companies exhibit relatively smaller idiosyncratic risk. The use of such variables as an extra adjustment factor can improve the accuracy of idiosyncratic risk estimates.

As mentioned before, idiosyncratic returns of different issuers are assumed to be uncorrelated. However, different securities from the same issuer can show a certain level of co-movement, as they are all exposed to specific events affecting their common issuer.

Interestingly, this co-movement is not perfect or static. Certain news can potentially affect the different securities issued by the same company (e.g., equity, bonds, or equity options) in different ways. Moreover, this relationship changes with the particular circumstances of the firm. For instance, returns from securities with claims to the assets of the firm should be more highly correlated if the firm is in distress. A good risk model should be able to capture these phenomena.

APPLICATIONS OF EQUITY RISK MODELS

Multifactor equity risk models are employed in various applications such as the quantitative analysis of portfolio risk, hedging unwanted exposures, portfolio construction, scenario

analysis, and performance attribution. In this section we discuss and illustrate some of these applications.

Portfolio managers can be divided broadly into indexers (those that measure their returns relative to a benchmark index) and absolute return managers (typically hedge fund managers). In between stand the enhanced indexers, those that are allowed to deviate from the benchmark index in order to express views, presumably leading to superior returns. All are typically subject to a risk budget that prescribes how much risk they are allowed to take to achieve their objectives: minimize transaction costs and match the index return for the pure indexers, maximize the net return for the enhanced indexers, or maximize absolute return for absolute return managers. In all of these cases, the manager has to merge all her views and constraints into a final portfolio.

The investment process of a typical portfolio manager involves several steps. Given the investment universe and objective, the steps usually consist of portfolio construction, risk prediction, and performance evaluation. These steps are iterated throughout the investment cycle over each rebalancing period. The examples in this section are constructed following these steps. In particular, we start with a discussion on the portfolio construction process for three equity portfolio managers with different goals: The first aims to track a benchmark, the second to build a momentum portfolio, and the third to implement sector views in a portfolio. We conduct these exercises through a risk-based portfolio optimization approach at a monthly rebalancing frequency. For the index-tracking portfolio example, we then conduct a careful evaluation of its risk exposures and contributions to ensure that the portfolio manager's views and intuition coincide with the actual portfolio exposures. Once comfortable with the positions and the associated risk, the portfolio is implemented. At the end of the monthly investment cycle, the performance of the portfolio and return contributions of its different compo-

nents can be evaluated using performance attribution.

Scenario analysis can be employed in both the portfolio construction and the risk evaluation phases of the portfolio process. This exercise allows the manager to gain additional intuition regarding the exposures of her portfolio and how it may behave under particular economic circumstances. It usually takes the form of stress testing the portfolio under historical or hypothetical scenarios. It can also reveal the sensitivity of the portfolio to particular movements in economic and financial variables not explicitly considered during the portfolio construction process. The last application in this entry illustrates this kind of analysis.

Throughout our discussion, we use a suite of global cash equity risk models available through POINT[®], the Barclays portfolio analytics and modeling platform.⁷

Portfolio Construction

Broadly speaking there are two main approaches to portfolio construction: a formal quantitative optimization-based approach and a qualitative approach that is based primarily on manager intuition and skill. There are many variations within and between these two approaches. In this section, we focus on risk-based optimization using a linear factor model. We do not discuss other more qualitative or nonrisk-based approaches (e.g., a stratified sampling). A common objective in a risk-based optimization exercise is the minimization of volatility of the portfolio, either in isolation or when evaluated against a benchmark. In the context of multifactor risk models, total volatility is composed of a systematic and an idiosyncratic component, as described above. Typically, both of these components are used in the objective function of the optimization problems. We demonstrate three different portfolio construction exercises and discuss how equity factor models are employed in this endeavor. The examples were constructed using the POINT[®] Optimizer.⁸ All

optimization problems were run as of July 30, 2010.

Tracking an Index

In our first example, we study the case of a portfolio manager whose goal is to create a portfolio that tracks a benchmark equity index as closely as possible, using a limited number of stocks. This is a very common problem in the investment industry since most assets under management are benchmarked to broad market indexes. Creating a benchmark-tracking portfolio provides a good starting point for implementing strategic views relative to that benchmark. For example, a portfolio manager might have a mandate to outperform a benchmark under particular risk constraints. One way to implement this mandate is to dynamically tilt the tracking portfolio toward certain investment styles based on views on the future performance of those styles at a particular point in the business cycle.

Consider a portfolio manager who is benchmarked to the S&P 500 index and aims to build a tracking portfolio composed of long-only positions from the set of S&P 500 stocks. Because of transaction cost and position management limitations, the portfolio manager is restricted to a maximum number of 50 stocks in the tracking portfolio. Her objective is to minimize the tracking error volatility (TEV) between her portfolio and the benchmark. Tracking error volatility can be described as the volatility of the return differential between the portfolio and the benchmark (i.e., measures a typical movement in this net position). A portfolio's TEV is commonly referred to as the risk or the (net) volatility of the portfolio.

As mentioned before, the total TEV is decomposed into a systematic TEV and an idiosyncratic TEV. Moreover, because these two components are assumed to be independent,

$$\begin{aligned} \text{Total TEV} &= \sqrt{\text{Systematic TEV}^2 + \text{Idiosyncratic TEV}^2} \end{aligned}$$

Table 2 Total Risk of Index-Tracking Portfolio vs. the Benchmark (bps/month)

Attribute	Realized Value
Total TEV	39.6
Idiosyncratic TEV	35.8
Systematic TEV	16.9

The minimization of systematic TEV is achieved by setting the portfolio's factor exposures (net of benchmark) as close to zero as possible, while respecting other potential constraints of the problem (e.g., maximum number of 50 securities in the portfolio). The minimization of idiosyncratic volatility is achieved through the diversification of the portfolio holdings.

Table 2 illustrates the total risk for portfolio versus benchmark that comes out of the optimization problem. We see that total TEV of the net position is 39.6 bps/month with 16.9 bps/month of systematic TEV and 35.8 bps/month of idiosyncratic TEV. If the portfolio manager wants to reduce her exposure to name-specific risk, she can increase the upper bound on the number of securities picked by the optimizer to construct the optimal portfolio (increasing the diversification effect). Another option would be to increase the relative weight of idiosyncratic TEV compared to the systematic TEV in the objective function. The portfolio resulting from this exercise would have smaller idiosyncratic risk but, unfortunately, would also have higher systematic risk. This trade-off can be managed based on the portfolio manager's preferences.

Figure 1 depicts the distribution of the position amount for individual stocks in the portfolio. We can see that the portfolio is well diversified across the 50 constituent stocks with no significant concentrations in any of the individual positions. The largest stock position is 4.1%, about three times larger than the smallest holding. Later in this entry, we analyze the risk of this particular portfolio in more detail.

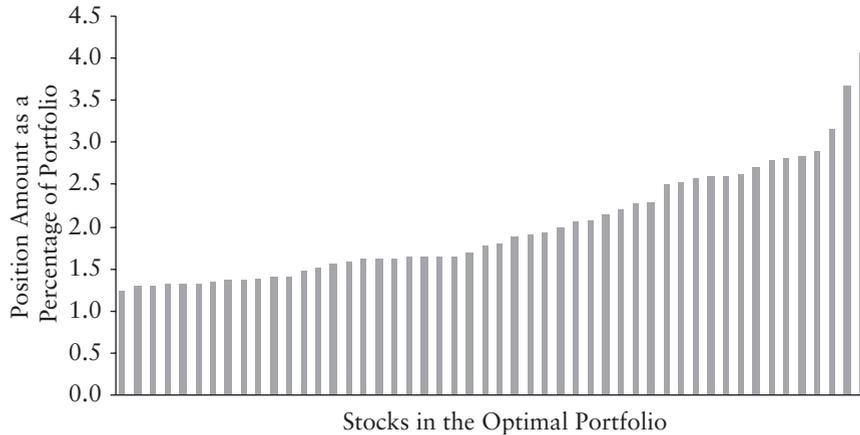

Figure 1 Position Amount of Individual Stocks in the Optimal Tracking Portfolio

Constructing a Factor-Mimicking Portfolio

Factor-mimicking portfolios allow portfolio managers to capitalize on their views on various investment themes. For instance, the portfolio manager may forecast that small-cap stocks will outperform large-cap stocks or that value stocks will outperform growth stocks in the near future. By constructing long-short factor-mimicking portfolios, managers can place positions in line with their views on these investment themes without taking explicit directional views on the broader market.

Considering another example, suppose our portfolio manager forecasts that recent winner (high momentum) stocks will outperform recent losers (low momentum). To implement her

views, she constructs two portfolios, one with winner stocks and one with loser stocks (100 stocks from the S&P 500 universe in each portfolio). She then takes a long position in the winners portfolio and a short position in the losers portfolio. While a sensible approach, a long-short portfolio constructed in this way would certainly have exposures to risk factors other than momentum. For instance, the momentum view might implicitly lead to unintended sector bets. If the portfolio manager wants to understand and potentially limit or avoid these exposures, she needs to perform further analysis. The use of a risk model will help her substantially.

To illustrate this point, table 3 shows one of POINT[®]'s risk model outputs—the 10

Table 3 Largest Risk Factor Exposures for the Momentum Winners/Losers Portfolio (bps/month)

largest risk factor exposures by their contribution to TEV (last column in the table) for the initial long-short portfolio. While momentum has the largest contribution to volatility, other risk factors also play a significant role. As a result, major moves in risk factors other than momentum can have a significant—and potentially unintended—impact on the portfolio's return.

Given this information, suppose our portfolio manager decides to avoid these exposures to the extent possible. She can do that by setting all exposures to factors other than momentum to zero (these type of constraints may not always be feasible and one may need to relax them to achieve a solution). Moreover, because she wants the portfolio to represent a pure systematic momentum effect, she seeks to minimize idiosyncratic risk. There are many ways to implement these additional goals, but increasingly portfolio managers are turning to risk models (using an optimization engine) to construct their portfolios in a robust and convenient way. She decides to set up an optimization problem where the objective function is the minimization of idiosyncratic risk. The tradable universe is the set of S&P 500 stocks and the portfolio is constructed to be dollar-neutral. This problem also incorporates the aforementioned factor exposure constraints.

The resulting portfolio (not shown) has exactly the risk factor exposures that were specified in the problem constraints. It exhibits a relatively low idiosyncratic TEV. Figure 2 depicts the largest 10 positions on the long and short sides of the momentum factor-mimicking portfolio; we see that there are no significant individual stock concentrations.

Implementing Sector Views

For our final portfolio construction example, let's assume we are entering a recessionary environment. An equity portfolio manager forecasts that the consumer staples sector will outperform the consumer discretionary sector in the near future, so she wants to create a portfolio to capitalize on this view. One simple idea would be to take a long position in the consumer staples sector (NCY: noncyclical) and a short position in the consumer discretionary sector (CYC: cyclical) by using, for example, sector ETFs. Similar to the previous example, this could result in exposures to risk factors other than the industry factors. Table 4 illustrates the exposure of this long-short portfolio to the risk factors in the POINT[®] U.S. equity risk model. As we can see in the table, the portfolio has significant net exposures to certain fundamental and technical factors, such as share turnover.

Suppose the portfolio manager decides to limit exposures to fundamental and technical factors. We can again use the optimizer to construct a long-short portfolio, with an exposure (beta) of 1 to the consumer staples sector and a beta of -1 to the consumer discretionary sector. To limit the exposure to fundamental and technical risk factors, we further impose the exposure to each of these factors to be between -0.2 and 0.2.⁹ We also restrict the portfolio to be dollar neutral, and allow for only long positions in the consumer staples stocks and for only short positions in consumer discretionary stocks. Finally, we restrict the investment universe to the members of the S&P 500 index.¹⁰

The resulting portfolio consists of 69 securities (approximately half of discretionary and staples stocks in S&P 500) with 31 long positions in the consumer staples stocks and 38 short positions in consumer discretionary stocks. Table 5 depicts the factor exposures for this portfolio. As we can see in the table, the sum

of the exposures to the industry factors is 1 for the consumer staples stocks and -1 for the consumer discretionary stocks. Exposures to fundamental and technical factors are generally significantly smaller when compared to the previous table, limiting the adverse effects of potential moves in these factors. Interestingly, no stocks from the automobiles industry are selected in the optimal portfolio, potentially due to excessive idiosyncratic risk of firms in that particular industry. The contribution to volatility from the cyclical sector is higher than that from the non-cyclical sector, due to higher volatility of industry factors in the former.

The bounds used for the fundamental and technical factor exposures in the portfolio construction process were set to force a reduction in the exposure to these factors. However, there is a trade-off between having smaller exposures and having smaller idiosyncratic risk in the final portfolio. The resolution of this trade-off depends on the preferences of the portfolio

manager. When the bounds are more restrictive, we are also decreasing the feasible set of solutions available to the problem and therefore potentially achieving a higher idiosyncratic risk (remember that the objective is the minimization of idiosyncratic risk). In our example, the idiosyncratic TEV of the portfolio increases from 119 bps/month (before the optimization) to 158 bps/month on the optimized portfolio. This change is the price paid for the ability to limit certain systematic risk factor exposures.

Analyzing Portfolio Risk Using Multifactor Models

Now that we have seen examples of using multifactor equity models for portfolio construction and briefly discussed their risk outcomes, we take a more in-depth look at portfolio risk. Risk analysis based on multifactor models can take many forms, from a relatively high-level aggregate approach to an in-depth analysis of the risk properties of individual stocks and groups of stocks. Multifactor equity risk models provide

the tools to perform the analysis of portfolio risk in many different dimensions, including exposures to risk factors, security factor contributions to total risk, analysis at the ticker level, and scenario analysis. In this section, we provide an overview of such detailed analysis using the S&P 500 index tracker example we created in the previous section.

Recall from Table 2 that the TEV of the optimized S&P 500 tracking portfolio was 39.6 bps/month, composed mostly of idiosyncratic risk (35.8 bps/month) and a relatively small amount of systematic risk (16.9 bps/month). To analyze further the source of these numbers, we first compare the holdings of the portfolio with those of the benchmark and then study the impact of the mismatch to the risk of the net position (Portfolio-Benchmark). The first column in Table 6 shows the net market weights (NMW) of the portfolio at the sector level (GICS level 1). Our portfolio appears to be well balanced with respect to the benchmark from a net market weight perspective. The largest market value discrepancies are an overweight in information

Table 6 Net Market Weights and Risk Contributions by Sector (bps/month)

	Net Market Weight (%)	Contribution to TEV (CTEV)		
		Systematic	Idiosyncratic	Total
Total	0.0	7.2	32.7	39.8
Energy	1.4	1.3	4.4	5.7
Materials	-2.1	1.0	1.3	2.3
Industrials	2.1	0.3	3.8	4.1
Consumer discretionary	-3.6	1.7	4.7	6.3
Consumer staples	-0.5	0.5	2.2	2.6
Health care	-3.3	1.3	2.2	3.4
Financials	0.1	0.6	7.0	7.5
Information tech	5.2	0.6	5.5	6.1
Telecom services	2.4	0.2	0.8	1.0
Utilities	-1.7	-0.1	0.9	0.8

technology (+5.2%) and an underweight in consumer discretionary (-3.6%) and health care (-3.3%) companies. However, the sector with the largest contribution to overall risk (contribution to TEV, or CTEV) is financials (7.5 bps/month). This may seem unexpected, given the small NMW of this sector (0.1%). This result is explained by the fact that contributions to risk (CTEV) are dependent on the net market weight of an exposure, its risk and also the correlation between the different exposures. Looking into the decomposition of the CTEV, the table also shows that most of the total contribution to risk from financials is idiosyncratic (7.0 bps/month). This result is due to the

small number of securities our portfolio has in this sector and the underlying high volatility of these stocks. In short, the diversification benefits across financial stocks are small in our portfolio: We could potentially significantly reduce total risk by constructing our financials exposure using more names. Note that this analysis is only possible with a risk model.

Table 7 highlights additional risk measures by sector. What we see in the first column is the isolated TEV, that is, the risk associated with the stocks in that particular sector only. On an isolated basis, the information technology sector has the highest risk in the portfolio. This top position in terms of isolated risk does not

Table 7 Additional Risk Measures by Sector

	Isolated TEV (bps/month)	Liquidation Effect on TEV (bps/month)	TEV Elasticity (x100) (bps)	Systematic Beta (bps)
Total	39.64	-39.64	100.00	1.00
Energy	13.94	-3.38	14.25	0.89
Materials	16.94	1.29	5.74	1.25
Industrials	20.99	1.41	10.27	1.20
Consumer discretionary	29.34	4.25	15.89	1.11
Consumer staples	10.70	-1.20	6.59	0.70
Health care	17.37	0.37	8.56	0.65
Financials	20.77	-2.19	18.93	1.34
Information tech	31.90	6.20	15.30	0.99
Telecom services	11.58	0.67	2.53	0.76
Utilities	10.30	0.56	1.93	0.79

translate into the highest contribution to overall portfolio risk, as we saw in Table 6. The discrepancy between isolated risk numbers and contributions to risk is explained by the correlation between the exposures and allows us to understand the potential hedging effects present across our portfolio. The liquidation effect reported in the table represents the change in TEV when we completely hedge that particular position, that is, enforce zero net exposure to any stock in that particular sector. Interestingly, eliminating our exposure to information technology stocks would actually increase our overall portfolio risk by 6.2 bps/month. This happens because the overweight in this sector is effectively hedging out risk contributions from other sectors. If we eliminate this exposure, the portfolio balance is compromised. The TEV elasticity reported gives an additional perspective regarding how the TEV in the portfolio changes when we change the exposure to that sector. Specifically, it tells us the percentage change in TEV for each 1% change in our exposure to that particular sector. For example, if we double our exposure to the energy sector, our TEV would increase by 14.25% (from 39.6 bps/month to 45.2 bps/month). Finally, the report estimates the portfolio to have a beta of 1.00 to the benchmark, which is, of course, in line with our index tracking objective. The beta statistic measures the comovement between the systematic risk drivers of the portfolio and the benchmark and should be interpreted only as that. In particular, a low portfolio beta (relative to the benchmark) does not imply low portfolio risk. It signals relatively low systematic co-movement between the two universes or a relatively high idiosyncratic risk for the portfolio. For example, if the sources of systematic risk from the portfolio and the benchmark are distinct, the portfolio beta is close to zero. The report also provides the systematic beta associated with each sector. For instance, we see that a movement of 1% in the benchmark leads to a 1.34% return in the financials component of

our portfolio. As expected, consumer staples and health care are two low beta industries, as they tend to be more stable through the business cycle.¹¹

Although important, the information we examined so far is still quite aggregated. For instance, we know from Table 6 that a large component of idiosyncratic risk comes from financials. But what names are contributing most? What are the most volatile sectors? How are systematic exposures distributed within each sector? Risk models should be able to provide answers to all these questions, allowing for a detailed view of the portfolio's risk exposures and contributions. As an example, Table 8 displays all systematic risk factors the portfolio or the benchmark loads onto. It also provides the portfolio, benchmark, and net exposures for each risk factor, the volatility of each of these factors, and their contributions to total TEV. The table shows that the net exposures to the risk factors are generally low, meaning that the tracking portfolio has small active exposures. This finding is in line with the evidence from Table 2, where we see that the systematic risk is small (16.9 bps/month). If we look into the contributions of individual factors to total TEV, the table shows that the top contributors are the size, share turnover, and realized volatility factors. The optimal index tracking portfolio tends to be composed of very large-cap names within the specified universe, and that explains the net positive loading to the market value (size) factor. This portfolio tilt is due to the generally low idiosyncratic risk large companies have. This is seen favorably by the optimization engine, as it tries to minimize idiosyncratic risk. This same tilt would explain our net exposure to both the share turnover and realized volatility factors, as larger companies tend to have lower realized volatility and share turnover too. Interestingly, industry factors have relatively small contributions to TEV, even though they exhibit significantly higher volatilities. This results from the fact that the optimization

Table 8 Factor Exposures and Contributions for the Tracking Portfolio vs. S&P 500 (bps/month)

U.S. Equity Other Market Volatility	Market weight	1.00	1.00	0.00	17	0.00

engine specifically targets these factors because of their high volatility and is successful in minimizing net exposure to industry factors in the final portfolio.

Finally, remember from Table 2 that the largest component of the portfolio risk comes from name-specific exposures. Therefore, it is important to be aware of which individual stocks in our portfolio contribute the most to overall risk. Table 9 shows the set of stocks in our portfolio with the largest idiosyncratic risk. The portfolio manager can use this information as a screening device to filter out undesirable positions with high idiosyncratic risk and to make sure her views on individual firms translate into risk as expected. In particular, the list in the table should only include names about which the portfolio manager has strong views, either positive—expressed with positive NMW—or negative—in which case we would expect a short net position.

It should be clear from the above examples that although the factors used to measure risk are predetermined in a linear factor model, there is a large amount of flexibility on the way the risk numbers can be aggregated and reported. Instead of sectors, we could have grouped risk by any other classification of individual stocks, for example, by regions or market capitalization. This allows the risk to be reported using the same investment philosophy underlying the portfolio construction process¹² regardless of the underlying factor model.

There are also many other risk analytics available, not mentioned in this example, that give additional detail about specific risk properties of the portfolio and the constituents. We have only discussed total, systematic, and idiosyncratic risk (which can be decomposed into risk contributions on a flexible basis), and referred to isolated and liquidation TEV, TEV elasticity, and portfolio beta. Most users of multifactor risk models will find their own preferred approach to risk analysis through experience.

Performance Attribution

Now that we discussed portfolio construction and risk analysis as the first steps of the investment process, we give a brief overview of performance attribution, an ex post analysis of performance typically conducted at the end of the investment horizon. Performance attribution analysis provides an evaluation of the portfolio manager's performance with respect to various decisions made throughout the investment process. The underperformance or outperformance of the portfolio manager when compared to the benchmark can be due to different reasons, including effective sector allocation, security selection, or tilting the portfolio toward certain risk factors. Attribution analysis aims to unravel the major sources of this performance differential. The exercise allows the portfolio manager to understand how her particular views—translated into net

Table 9 Individual Securities and Idiosyncratic Risk Exposures

Company Name	Portfolio Weight (%)	Benchmark Weight (%)	Net Weight (%)	Idiosyncratic TEV (bps/month)
Vornado Realty Trust	2.80	0.13	2.67	7.42
Kohls Corp	1.41	0.15	1.26	6.58
Bank of America Corp	2.71	1.41	1.29	6.16
Conocophillips	2.29	0.82	1.47	6.03
Roper Industries Inc	1.62	0.06	1.56	5.98
Walt Disney Co	2.26	0.66	1.60	5.48
Honeywell International Inc.	2.58	0.33	2.25	5.48
Cincinnati Financial Corp	1.88	0.05	1.83	5.35
Goldman Sachs	0.00	0.78	-0.78	5.25

exposures—performed during the period and reveals whether some of the portfolio's performance was the result of unintended bets.

There are three basic forms of attribution analysis used for equity portfolios. These are return decomposition, factor model-based attribution, and style analysis. In the return decomposition approach, the performance of the portfolio manager is generally attributed to top-down allocation (e.g., currency, country, or sector allocation) in a first step, followed by a bottom-up security selection performance analysis. This is a widely used technique among equity portfolio managers.

Factor model-based analysis attributes performance to exposures to risk factors such as industry, size, and financial ratios. It is relatively more complicated than the previous approach and is based on a particular risk model that needs to be well understood. For example, let's assume that a portfolio manager forecasts that value stocks will outperform growth stocks in the near future. As a result, the manager tilts the portfolio toward value stocks as compared to the benchmark, creating an active exposure to the value factor. In an attribution framework without systematic factors, such sources of performance cannot be identified and hence may be inadvertently attributed to other reasons. Factor model-based attribution analysis adds value by incorporating these factors (representing major investment themes) explicitly into the return decomposition process and by identifying additional sources of performance represented as active exposures to systematic risk factors.

Style analysis, on the other hand, is based on a regression of the portfolio return to a set of style benchmarks. It requires very little information (e.g., we do not need to know the contents of the portfolio), but the outcome depends significantly on the selection of style benchmarks. It also assumes constant loadings to these styles across the regression period, which may be unrealistic for managers with somewhat dynamic allocations.

Factor-Based Scenario Analysis

The last application we review goes over the use of equity risk factor models in the context of scenario analysis. Many investment professionals utilize scenario analysis in different shapes and forms for both risk and portfolio construction purposes. Factor-based scenario analysis is a tool that helps portfolio managers in their decision-making process by providing additional intuition on the behavior of their portfolio under a specified scenario. A scenario can be a historical episode, such as the equity market crash of 1987, the war in Iraq, or the 2008 credit crisis. Alternatively, scenarios can be defined as a collection of hypothetical views (e.g., user-defined scenarios) in a variety of forms such as a view on a given portfolio or index (e.g., S&P 500 drops by 20%) or a factor (e.g., U.S. equity-size factor moves by 3 standard deviations) or correlation between factors (e.g., increasing correlations across markets in episodes of flight to quality). In this section, we use the POINT[®] Factor-Based Scenario Analysis Tool to illustrate how we can utilize factor models to perform scenario analysis.

Before we start describing the example, let's take an overview of the mechanics of the model. It allows for the specification of user views on returns of portfolios, indexes, or risk factors. When the user specifies a view on a portfolio or index, this is translated into a view on risk factor realizations, through the linear factor model framework.¹³ These views are combined with ones that are directly specified in terms of risk factors. It is important to note that the portfolio manager does not need to specify views on all risk factors, and typically has views only on a small subset of them. Once the manager specifies this subset of original views, the next step is to expand these views to the whole set of factors. The scenario analysis engine achieves this by estimating the most likely realization of all other factors—given the factor realizations on which views are specified—using the risk model covariance matrix. Once all factor

Table 10 Index Returns under Scenario 1 (VIX jumps by 50%)

Universe	Type	Measure	Unit	Result
S&P 500	Equity index	Return	%	-7.97
FTSE U.K. 100	Equity index	Return	%	-9.34
DJ EURO STOXX 50	Equity index	Return	%	-11.63
NIKKEI 225	Equity index	Return	%	-4.99
MSCI-AC ASIA PACIFIC EX JAPAN	Equity index	Return	%	-10.33
MSCI-EMERGING MARKETS	Equity index	Return	%	-9.25

realizations are populated, the scenario outcome for any portfolio or index can be computed by multiplying their specific exposures to the risk factors by the factor realizations under the scenario. The tool provides a detailed analysis of the portfolio behavior under the specified scenario.

We illustrate this tool using two different scenarios: a 50% shift in the U.S. equity market volatility—represented by the VIX index—(scenario 1) and a 50% jump in the European credit spreads (scenario 2).¹⁴ We use a set of equity indexes from across the globe to illustrate the impact of these two scenarios. We run the scenarios as of July 30, 2010, which specifies the date both for the index loadings and the covariance matrix used. Base currency is set to U.S. dollars (USD) and hence index returns presented below are in USD.

Table 10 shows the returns of the chosen equity indexes under the first scenario. We see that all indexes experience significant negative returns with Euro Stoxx plummeting the most

and Nikkei experiencing the smallest drop. To understand these numbers better, let's look into the contributions of different factors to these index returns.

Table 11 illustrates return contributions for four of these equity indexes under scenario 1. Specifically, for each index, it decomposes the total scenario return into return coming from different factors each index has exposure to. In this example, all currency factors are defined with respect to USD. Moreover, equity factors are expressed in their corresponding local currencies and can be described as broad market factors for their respective regions.

Not surprisingly, Table 11 shows that the majority of the return contributions for selected indexes come from the reaction of equity market factors to the scenario. However, foreign exchange (FX) can also be a significant portion of total return for some indexes, such as in the case of the Euro Stoxx (-4.8%). Nikkei experiences a relatively smaller drop in USD terms, majorly due to a positive contribution coming from the

Table 11 Return Contributions for Equity Indexes under Scenario 1 (in %)

Group	Factor	S&P 500	FTSE U.K. 100	DJ EURO STOXX 50	NIKKEI 225
FX	GBP		-1.77		
FX	JPY				1.21
FX	EUR		-0.38	-4.80	
Equity	U.S. equity	-7.97			
Equity	U.K. equity		-6.67		
Equity	Japan equity				-6.20
Equity	EMG equity		-0.09		
Equity	Continental Europe equity		-0.43	-6.83	
Total		-7.97	-9.34	-11.63	-4.99

Table 12 Factor Returns and Z-Scores under Scenario 1

Group	Name	Measure	Unit	Value	Std. Dev.	Z-Score
Equity	U.K. equity	Return	%	-7.85	4.99	-1.57
Equity	U.S. equity	Return	%	-8.61	6.06	-1.42
Equity	Continental Europe equity	Return	%	-7.12	5.04	-1.41
Equity	Japan equity	Return	%	-5.96	4.73	-1.26
Equity	EMG equity	Return	%	-8.50	6.88	-1.24
FX	EUR	Return	%	-4.80	3.93	-1.22
FX	GBP	Return	%	-1.93	3.42	-0.56
FX	JPY	Return	%	1.21	3.39	0.36

JPY FX factor. This positive contribution is due to the safe haven nature of Japanese yen in case of flight to quality under increased risk aversion in global markets.

Table 12 demonstrates the scenario-implied factor realizations (“value”), factor volatilities, and the Z-scores for the risk factors given in Table 11. The Z-score of the factor quantifies the effect of the scenario on that specific factor. It is computed as

$$z = \frac{r}{\sigma_r}$$

where r is the return of the factor in the scenario and σ_r is the standard deviation of the factor. Hence, the Z-score measures how many standard deviations a factor moves in a given scenario. Table 12 lists the factors by increasing Z-score under scenario 1. The U.K. equity factor experiences the largest negative move, at -1.57 standard deviations. FX factors experience relatively smaller movements. JPY is the only factor with a positive realization due to the aforementioned characteristic of the currency.

In the second scenario, we shift European credit spreads by 50% (a 3.5-sigma event) and explore the effect of credit market swings on the equity markets. As we can see in Table 13, all equity indexes experience significant returns, in line with the severity of the scenario.¹⁵ The result also underpins the strong recent co-movement between the credit and equity markets. The exception is again the Nikkei that realizes a relatively smaller return.

Table 14 provides the return, volatility, and the Z-score of certain relevant factors under scenario 2. As expected, the major mover on the equity side is the continental Europe equity factor, followed by the United Kingdom. Given the recent strong correlations between equity and credit markets across the globe, the table suggests that a 3.5 standard deviation shift in the European spread factor results in a 2 to 3 standard deviation movement of global equity factors.

The two examples above illustrate the use of factor models in performing scenario analysis to achieve a clear understanding of how a portfolio may react under different circumstances.

Table 13 Index Returns under Scenario 2 (EUR Credit Spread Jumps by 50%)

Universe	Type	Measure	Unit	Result
S&P 500	Equity index	Return	%	-13.03

FX	EUR	Return	%	-6.23	3.93	-1.59
FX	JPY	Return	%	3.07	3.39	0.90

KEY POINTS

- Multifactor equity risk models provide detailed insight into the structure and properties of portfolios. These models characterize stock returns in terms of systematic factors and an idiosyncratic component. Systematic factors are generally designed to have intuitive economic interpretation and they represent common movements across securities. On the other hand, the idiosyncratic component represents the residual return due to stock-specific events.
- Systematic factors used in equity risk models can be broadly classified under five categories: market factors, classification variables, firm characteristics, macroeconomic variables, and statistical factors.
- Relative significance of systematic risk factors depends on various parameters such as the model horizon, region/country for which the model is designed, existence of other factors, and the particular time period of the analysis. For instance, in the presence of industry factors, macroeconomic factors tend to be insignificant for short to medium horizon equity risk models whereas they tend to be more significant for long-horizon models. Moreover, for developed equity markets, industry factors are typically more significant as compared to the country factors. The latter are still the dominant effect for emerging markets.
- Choice of the model and the estimation technique affect the interpretation of factors. For instance, in the existence of a market factor, industry factors represent industry-specific movements net of market. If there is no market factor, their interpretation is very close to market value-weighted industry indexes.
- Multifactor equity risk models can be classified according to how their loadings and factors are specified. The most common equity factor models specify loadings based on classification (e.g., industry) and fundamental or technical information, and estimate factor realizations every period. Certain other models take factors as known (e.g., returns on industry indexes) and estimate loadings based on time-series information. A third class of models is based purely on statistical approaches without concern for economic interpretation of factors and loadings. Finally, it is possible to combine these approaches and construct hybrid models. Each of these approaches has its own specific strengths and weaknesses.
- A good multifactor equity risk model provides detailed information regarding the exposures of a complex portfolio and can be a valuable tool for portfolio construction and risk management. It can help managers construct portfolios tracking a particular benchmark, express views subject to a given risk budget, and rebalance a portfolio

while avoiding excessive transaction costs. Further, by identifying the exposures where the portfolio has the highest risk sensitivity it can help a portfolio manager reduce (or increase) risk in the most effective way.

- Performance attribution based on multifactor equity risk models can give ex post insight into how the portfolio manager's views and corresponding investments translated into actual returns.
- Factor-based scenario analysis provides portfolio managers with a powerful tool to perform stress testing of portfolio positions and gain insight into the impact of specific market events on portfolio performance.

NOTES

1. The Barclays Global Risk Model is available through POINT[®], Barclays portfolio management tool. It is a multicurrency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a covariance matrix of risk factors. The model has more than 500 factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such a large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.
2. As an example, if the portfolio has 10 stocks, we need to estimate 45 parameters, with 100 stocks we would need to estimate 4,950 parameters.
3. This is especially the case over crisis periods where stock characteristics can change dramatically over very short periods of time.
4. Fixed income managers typically use cross-sectional type of models.
5. GICS is the Global Industry Classification Standard by Standard & Poor's, a widely used classification scheme by equity portfolio managers.
6. An application of macro variables in the context of risk factor models is as follows. First, we get the sensitivities of the portfolio to the model's risk factors. Then we project the risk factors into the macro variables. We then combine the results from these two steps to get the indirect loadings of the portfolio to the macro factors. Therefore, instead of calculating the portfolio sensitivities to macro factors by aggregating individual stock macro sensitivities—that are always hard to estimate—we work with the portfolio's macro loadings, estimated indirectly from the portfolio's risk factor loadings as described above. This indirect approach may lead to statistically more robust relationships between portfolio returns and macro variables.
7. The equity risk model suite in POINT consists of six separate models across the globe: the United States, United Kingdom, Continental Europe, Japan, Asia (excluding Japan), and global emerging markets equity risk models (for details see Silva, Staal, and Ural, 2009). It incorporates many unique features related to factor choice, industry and fundamental exposures, and risk prediction.
8. See Kumar (2010).
9. The setting of these exposures and its trade-offs are discussed later in this entry.
10. As POINT[®] U.S. equity risk model incorporates industry level factors, a unit exposure to a sector is implemented by restricting exposures to different industries within that sector to sum up to 1. Also, note that as before, the objective in the optimization problem is the minimization of idiosyncratic TEV to ensure that the resulting portfolio represents systematic—not idiosyncratic—effects.

11. Note that we can sum the sector betas into the portfolio beta, using portfolio sector weights (not net weights) as weights in the summation.
12. For a detailed methodology on how to perform this customized analysis, see Silva (2009).
13. Specifically, we can back out factor realizations from the portfolio or index returns by using their risk factor loadings.
14. For reference, as of July 30, 2010, scenario 1 would imply the VIX would move from 23.5 to 35.3 and scenario 2 would imply that the credit spread for the Barclays European Credit Index would change from 174 bps to 261 bps.
15. The same scenario results in a -8.12% move in the Barclays Euro Credit Index.

Abstract: A factor is a common character among a group of assets. In the equities market, for example, it could be a particular financial ratio such as the price-earnings ratio or the book-price ratio. Factors fall into three categories—macroeconomic influences, cross-sectional characteristics, and statistical factors. Within asset management firms, factors and factor-forecasting models are used for a number of purposes. Those purposes could be central to managing portfolios. Within a trading strategy, for example, factors determine when to buy and sell securities. Factors are employed in other areas of financial theory, such as asset pricing, risk management, and performance attribution.

Common stock investment strategies can be broadly classified into the following categories: (1) *factor-based trading* strategies (also called *stock selection* or alpha models), (2) statistical arbitrage, (3) high-frequency strategies, and (4) event studies. Factors and factor-based models form the core of a major part of today's quantitative trading strategies. The focus of this entry is on developing trading strategies based on factors constructed from common (cross-sectional) characteristics of stocks. For this purpose, first we provide a definition of factors. We then examine the major sources of risk associated with trading strategies, and demonstrate how factors

are constructed from company characteristics and market data. The quality of the data used in this process is critical. We examine several data cleaning and adjustment techniques to account for problems occurring with backfilling and restatements of data, missing data, inconsistently reported data, as well as survivorship and look-ahead biases. In the last section of this entry, we discuss the analysis of the statistical properties of factors.

In a series of examples, we show the individual steps for developing a basic trading strategy. The purpose of these examples is not to provide yet another profitable trading strategy,

but rather to illustrate the process an analyst may follow when performing research. In fact, the factors that we use for this purpose are well known and have for years been exploited by industry practitioners. The value added of these examples is in the concrete illustration of the research and development process of a factor-based trading model.

FACTOR-BASED TRADING

Since the first version of the classic text on security analysis by Benjamin Graham and David Dodd¹—considered to be the Bible on the fundamental approach to security analysis—was first published in 1934, equity portfolio management and trading strategies have developed considerably. Graham and Dodd were early contributors to factor-based strategies because they extended traditional valuation approaches by using information throughout the financial

statements² and by presenting concrete rules of thumb to be used to determine the attractiveness of securities.³

Today's quantitative managers use factors as fundamental building blocks for trading strategies. Within a trading strategy, factors determine when to buy and sell securities. We define a *factor* as a common characteristic among a group of assets. In the equities market, it could be a particular financial ratio such as the price–earnings (P/E) or the book–price (B/P) ratios. Some of the most well-known factors and their underlying basic economic rationale references are provided in Table 1.

Most often this basic definition is expanded to include additional objectives. First, factors frequently are intended to capture some economic intuition. For instance, a factor may help understand the prices of assets by reference to their exposure to sources of macroeconomic risk, fundamental characteristics, or basic market behavior. Second, we should recognize that

Table 1 Summary of Well-Known Factors and Their Underlying Economic Rationale

Factor	Economic Rationale
Dividend yield	Investors prefer to immediately receive receipt of their investment returns.
Value	Investors prefer stocks with low valuations.
Size (market capitalization)	Smaller companies tend to outperform larger companies.
Asset turnover	This measure evaluates the productivity of assets employed by a firm. Investors believe higher turnover correlates with higher future return.
Earnings revisions	Positive analysts' revisions indicate stronger business prospects and earnings for a firm.
Growth of fiscal year 1 and fiscal year 2 earnings estimates	Investors are attracted to companies with growing earnings.
Momentum	Investors prefer stocks that have had good past performance.
Return reversal	Investors overreact to information, that is, stocks with the highest returns in the current month tend to earn lower returns the following month.
Idiosyncratic risk	Stocks with high idiosyncratic risk in the current month tend to have lower returns the following month.
Earnings surprises	Investors like positive earnings surprises and dislike negative earnings surprises.
Accounting accruals	Companies with earnings that have a large cash component tend to have higher future returns.
Corporate governance	Firms with better corporate governance tend to have higher firm value, higher profits, higher sales growth, lower capital expenditures, and fewer corporate acquisitions.
Executive compensation factors	Firms that align compensation with shareholders' interest tend to outperform.
Accounting risk factors	Companies with lower accounting risk tend to have higher future returns.

assets with similar factors (characteristics) tend to behave in similar ways. This attribute is critical to the success of a factor. Third, we would like our factor to be able to differentiate across different markets and samples. Fourth, we want our factor to be robust across different time periods.

Factors fall into three categories—macroeconomic influences, cross-sectional characteristics, and statistical factors. Macroeconomic influences are time series that measure observable economic activity. Examples include interest rate levels, gross domestic production, and industrial production. Cross-sectional characteristics are observable asset specifics or firm characteristics. Examples include dividend yield, book value, and volatility. Statistical factors are unobservable or latent factors common across a group of assets. These factors make no explicit assumptions about the asset characteristics that drive commonality in returns. Statistical factors are not derived using exogenous data but are extracted from other variables such as returns. These factors are calculated using various statistical techniques such as principal components analysis or factor analysis.

Within asset management firms, factors and forecasting models are used for a number of purposes. Those purposes could be central to managing portfolios. For example, a portfolio manager can directly send the model output to the trading desk to be executed. In other uses, models provide analytical support to analysts and portfolio management teams. For instance, models are used as a way to reduce the investable universe to a manageable number of securities so that a team of analysts can perform fundamental analysis on a smaller group of securities.

Factors are employed in other areas of financial theory, such as asset pricing, risk management, and performance attribution. In asset pricing, researchers use factors as proxies for common, undiversifiable sources of risk in the economy to understand the prices or values of

securities to uncertain payments. Examples include the dividend yield of the market or the yield spread between a long-term bond yield and a short-term bond yield.⁴ In risk management, risk managers use factors in risk models to explain and to decompose variability of returns from securities, while portfolio managers rely on risk models for covariance construction, portfolio construction, and risk measurement. In performance attribution, portfolio managers explain past portfolio returns based on the portfolio's exposure to various factors. Within these areas, the role of factors continues to expand. Recent research presents a methodology for attributing active return, tracking error, and the information ratio to a set of custom factors.⁵

The focus in this entry is on using factors to build equity forecasting models, also referred to as alpha or *stock selection models*. The models serve as mathematical representations of trading strategies. The mathematical representation uses future returns as dependent variables and factors as independent variables.

DEVELOPING FACTOR-BASED TRADING STRATEGIES

The development of a trading strategy has many similarities with an engineering project. We begin by designing a framework that is flexible enough so that the components can be easily modified, yet structured enough that we remain focused on our end goal of designing a profitable trading strategy.

Basic Framework and Building Blocks

The typical steps in the development of a trading strategy are:

- Defining a trading idea or investment strategy.
- Developing factors.

- Acquiring and processing data.
- Analyzing the factors.
- Building the strategy.
- Evaluating the strategy.
- Backtesting the strategy.
- Implementing the strategy.

In what follows, we take a closer look at each step.

Defining a Trading Idea or Investment Strategy

A successful trading strategy often starts as an idea based on sound economic intuition, market insight, or the discovery of an anomaly. Background research can be helpful in order to understand what others have tried or implemented in the past.

We distinguish between a trading idea and trading strategy based on the underlying economic motivation. A trading idea has a more short-term horizon often associated with an event or mispricing. A trading strategy has a longer horizon and is frequently based on the exploitation of a premium associated with an anomaly or a characteristic.

Developing Factors

Factors provide building blocks of the model used to build an investment strategy. We introduced a general definition of factors earlier in this entry. After having established the trading strategy, we move from the economic concepts to the construction of factors that may be able to capture our intuition. In this entry, we provide a number of examples of factors based on the cross-sectional characteristics of stocks.

Acquiring and Processing Data

A trading strategy relies on accurate and clean data to build factors. There are a number of third-party solutions and databases available for this purpose such as Thomson MarketQA,⁶

Factset Research Systems,⁷ and Compustat Xpressfeed.⁸

Analyzing the Factors

A variety of statistical and econometric techniques must be performed on the data to evaluate the empirical properties of factors. This empirical research is used to understand the risk and return potential of a factor. The analysis is the starting point for building a model of a trading strategy.

Building the Strategy

The model represents a mathematical specification of the trading strategy. There are two important considerations in this specification: the selection of which factors and how these factors are combined. Both considerations need to be motivated by the economic intuition behind the trading strategy. We advise against model specification being strictly data driven because that approach often results in overfitting the model and consequently overestimating forecasting quality of the model.

Evaluating, Backtesting, and Implementing the Strategy

The final step involves assessing the estimation, specification, and forecast quality of the model. This analysis includes examining the goodness of fit (often done in sample), forecasting ability (often done out of sample), and sensitivity and risk characteristics of the model.

RISK TO TRADING STRATEGIES

In investment management, risk is a primary concern. The majority of trading strategies are not risk free but rather subject to various risks. It is important to be familiar with the most

common risks in trading strategies. By understanding the risks in advance, we can structure our empirical research to identify how risks will affect our strategies. Also, we can develop techniques to avoid these risks in the model construction stage when building the strategy.

We describe the various risks that are common to factor trading strategies as well as other trading strategies such as risk arbitrage. Many of these risks have been categorized in the behavioral finance literature.⁹ The risks discussed include fundamental risk, noise trader risk, horizon risk, model risk, implementation risk, and liquidity risk.

Fundamental risk is the risk of suffering adverse fundamental news. For example, say our trading strategy focuses on purchasing stocks with high earnings-to-price ratios. Suppose that the model shows a pharmaceutical stock maintains a high score. After purchasing the stock, the company releases a news report that states it faces class-action litigation because one of its drugs has undocumented adverse side effects. While during this period other stocks with high earnings-to-price ratio may perform well, this particular pharmaceutical stock will perform poorly despite its attractive characteristic. We can minimize the exposure to fundamental risk within a trading strategy by diversifying across many companies. Fundamental risk may not always be company specific; sometimes this risk can be systemic. Some examples include the exogenous market shocks of the stock market crash in 1987, the Asian financial crisis in 1997, and the tech bubble in 2000. In these cases, diversification was not that helpful. Instead, portfolio managers that were sector or market neutral in general fared better.

Noise trader risk is the risk that a mispricing may worsen in the short run. The typical example includes companies that clearly are undervalued (and should therefore trade at a higher price). However, because noise traders may trade in the opposite direction, this mispricing can persist for a long time. Closely related to noise trader risk is *horizon risk*. The

idea here is that the premium or value takes too long to be realized, resulting in a realized return lower than a target rate of return.

Model risk, also referred to as *misspecification risk*, refers to the risk associated with making wrong modeling assumptions and decisions. This includes the choice of variables, methodology, and context the model operates in. There are different sources that may result in model misspecification and there are several remedies based on information theory, Bayesian methods, shrinkage, and random coefficient models.¹⁰

Implementation risk is another risk faced by investors implementing trading strategies. This risk category includes transaction costs and funding risk. Transaction costs such as commissions, bid-ask spreads, and market impact can adversely affect the results from a trading strategy. If the strategy involves shorting, other implementation costs arise such as the ability to locate securities to short and the costs to borrow the securities. *Funding risk* occurs when the portfolio manager is no longer able to get the funding necessary to implement a trading strategy. For example, many statistical arbitrage funds use leverage to increase the returns of their funds. If the amount of leverage is constrained, then the strategy will not earn attractive returns. Khandani and Lo (2007) confirm this example by showing that greater competition and reduced profitability of quantitative strategies today require more leverage to maintain the same level of expected return.

Liquidity risk is a concern for investors. Liquidity is defined as the ability to (1) trade quickly without significant price changes, and (2) trade large volumes without significant price changes. Cerniglia and Kolm (2009) discuss the effects of liquidity risk during the "quant crisis" in August 2007. They show how the rapid liquidation of quantitative funds affected the trading characteristics and price impact of trading individual securities as well as various factor-based trading strategies.

These risks can detract or contribute to the success of a trading strategy. It is obvious how these risks can detract from a strategy. What is not always clear is when any one of these unintentional risks contributes to a strategy. That is, sometimes when we build a trading strategy we take on a bias that is not obvious. If there is a premium associated with this unintended risk, then a strategy will earn additional return. Later the premium to this unintended risk may disappear. For example, a trading strategy that focuses on price momentum performed strongly in the calendar years of 1998 and 1999. What an investor might not notice is that during this period the portfolio became increasingly weighted toward technology stocks, particularly Internet-related stocks. During 2000, these stocks severely underperformed.

DESIRABLE PROPERTIES OF FACTORS

Factors should be founded on sound economic intuition, market insight, or an anomaly. In addition to the underlying economic reasoning, factors should have other properties that make them effective for forecasting.

It is an advantage if factors are intuitive to investors. Many investors will only invest in a particular fund if they understand and agree with the basic ideas behind the trading strategies. Factors give portfolio managers a tool in communicating to investors what themes they are investing in.

The search for the economic meaningful factors should avoid strictly relying on pure historical analysis. Factors used in a model should not emerge from a sequential process of evaluating successful factors while removing less favorable ones.

Most importantly, a group of factors should be parsimonious in its description of the trading strategy. This requires careful evaluation of the interaction between the different factors. For ex-

ample, highly correlated factors will cause the inferences made in a multivariate approach to be less reliable. Another possible problem when using multiple factors is the possibility of overfitting in the modeling process.

Any data set contains outliers, that is, observations that deviate from the average properties of the data. Outliers are not always trivial to handle and sometimes we may want to exclude them and other times not. For example, they could be erroneously reported or legitimate abnormal values. Later in this entry we discuss a few standard techniques to perform data cleaning. The success or failure of factors selected should not depend on a few outliers. In most cases, it is desirable to construct factors that are reasonably robust to outliers.

SOURCES FOR FACTORS

How do we find factors? The sources are widespread with no one source clearly dominating. Employing a variety of sources seems to provide the best opportunity to uncover factors that will be valuable for developing a new model.

There are a number of ways to develop factors based on economic foundations. It may start with thoughtful observation or study of how market participants act. For example, we may ask ourselves how other market participants will evaluate the prospects of the earnings or business of a firm. We may also want to consider what stock characteristics investors will reward in the future. Another common approach is to look for inefficiencies in the way that investors process information. For instance, research may discover that consensus expectations of earnings estimates are biased.

A good source for factors is the various reports released by the management of companies. Many reports contain valuable information and may provide additional context on how management interprets the company results and financial characteristics. For

example, quarterly earning reports (10-Qs) may highlight particular financial metrics relevant to the company and the competitive space they are operating within. Other company financial statements and SEC filings, such as the 10-K or 8-K, also provide a source of information to develop factors. It is often useful to look at the financial measures that management emphasize in their comments.

Factors can be found through discussions with market participants such as portfolio managers and traders. Factors are uncovered by understanding the heuristics experienced investors have used successfully. These heuristics can be translated into factors and models.

Wall Street analyst reports—also called sell-side reports or equity research reports—may contain valuable information. The reader is often not interested in the final conclusions, but rather in the methodology or metrics the analysts use to forecast the future performance of a company. It may also be useful to study the large quantity of books written by portfolio managers and traders that describe the process they use in stock selection.

Academic literature in finance, accounting, and economics provides evidence of numerous factors and trading strategies that earn abnormal returns. Not all strategies will earn abnormal profits when implemented by practitioners, for example, because of institutional constraints and transaction costs. Bushee and Raedy (2006) find that trading strategy returns are significantly decreased due to issues such as price pressure, restrictions against short sales, incentives to maintain an adequately diversified portfolio, and restrictions to hold no more than 5% ownership in a firm.

In uncovering factors, we should put economic intuition first and data analysis second. This avoids performing pure data mining or simply overfitting our models to past history. Research and innovation is the key to finding new factors. Today, analyzing and testing new factors and improving upon existing ones is itself a big industry.

BUILDING FACTORS FROM COMPANY CHARACTERISTICS

The following sections focus on the techniques for building factors from company characteristics. Often we desire our factors to relate the financial data provided by a company to metrics that investors use when making decisions about the attractiveness of a stock such as valuation ratios, operating efficiency ratios, profitability ratios, and solvency ratios. Factors should also relate to the market data such as analysts' forecasts, prices and returns, and trading volume.

WORKING WITH DATA

In this section, we discuss how to work with data and data quality issues, including some well-probed techniques used to improve the quality of the data. Though the role of getting and analyzing data can be mundane and tedious, we need not forget that high-quality data are critical to the success of a trading strategy. It is important to realize model output is only as good as the data used to calibrate it. As the saying goes: "Garbage in, garbage out."

Understanding the structure of financial data is important. We distinguish three different categories of financial data: time series, cross-sectional, and panel data. Time series data consist of information and variables collected over multiple time periods. Cross-sectional data consist of data collected at one point in time for many different companies (the cross-section of companies of interest). A panel data set consists of cross-sectional data collected at different points in time. We note that a panel data set may not be homogeneous. For instance, the cross-section of companies may change from one point in time to another.

Data Integrity

Quality data maintain several attributes such as providing a consistent view of history,

maintaining good data availability, containing no survivorship, and avoiding look-ahead bias. As all data sets have their limitations, it is important for the quantitative researcher to be able to recognize the limitations and adjust the data accordingly.

Data used in research should provide a consistent view of history. Two common problems that distort the consistency of financial data are backfilling and restatements of data. Backfilling of data happens when a company is first entered into a database at the current period and its historical data are also added. This process of backfilling data creates a selection bias because we now find historical data on this recently added company when previously it was not available. Restatements of data are prevalent in distorting consistency of data. For example, if a company revises its earnings per share numbers after the initial earnings release, then many database companies will overwrite the number originally recorded in the database with the newly released figure.

A frequent and common concern with financial databases is data availability. First, data items may only be available for a short period of time. For example, there were many years when stock options were granted to employees but the expense associated with the option grant was not required to be disclosed in financial statements. It was not until 2005 that accounting standards required companies to recognize directly stock options as an expense on the income statement. Second, data items may be available for only a subset of the cross-section of firms. Some firms, depending on the business they operate in, have research and development expenses while others do not. For example, many pharmaceutical companies have research and development expenses while utilities companies do not. A third issue is that a data item may simply not be available because it was not recorded at certain points in time. Sometimes this happens for just a few observations, other times it is the case for the whole time-series for a specific data item for a company. Fourth, dif-

ferent data items are sometimes combined. For example, sometimes depreciation and amortization expenses are not a separate line item on an income statement. Instead it is included in cost of goods sold. Fifth, certain data items are only available at certain periodicities. For instance, some companies provide more detailed financial reports quarterly while others report more details annually. Sixth, data items may be inconsistently reported across different companies, sectors, or industries. This may happen as the financial data provider translates financial measures from company reports to the specific database items (incomplete mapping), thereby ignoring or not correctly making the right adjustments.

For these issues some databases provide specific codes to identify the causes of missing data. It is important to have procedures in place that can distinguish among the different reasons for the missing data and be able to make adjustments and corrections.

Two other common problems with databases are survivorship and look-ahead bias. *Survivorship bias* occurs when companies are removed from the database when they no longer exist. For example, companies can be removed because of a merger or bankruptcy. This bias skews the results because only successful firms are included in the entire sample. Look-ahead bias occurs when data are used in a study that would not have been available during the actual period analyzed. For example, the use of year-end earnings data immediately at the end of the reporting period is incorrect because the data are not released by the firm until several days or weeks after the end of the reporting period.

Data alignment is another concern when working with multiple databases. Many databases have different identifiers used to identify a firm. Some databases have vendor specific identifiers, others have common identifiers such as CUSIPs or ticker symbols. Unfortunately, CUSIPs and ticker symbols change over time and are often reused. This practice makes

it difficult to link an individual security across multiple databases across time.

Example: The EBITDA/EV Factor

This example illustrates how the nuances of data handling can influence the results of a particular study. We use data from the Compustat Point-In-Time database and calculate the EBITDA/EV factor.¹¹ This factor is defined as earnings before interest, taxes, depreciation, and amortization divided by enterprise value (EBITDA/EV). Our universe of stocks is the Russell 1000 from December 1989 to December 2008, excluding financial companies. We calculate EBITDA /EV by two equivalent but different approaches. Each approach differs by the data items used in calculating the numerator (EBITDA):

1. EBITDA = Sales (Compustat data item 2) – Cost of goods sold (Compustat data item 30) – Selling and general administrative expenses (Compustat data item 1).
2. EBITDA = Operating income before depreciation (Compustat data item 21).

According to the Compustat manual, the following identity holds:

$$\begin{aligned} &\text{Operating income before depreciation} \\ &= \text{Sales} - \text{Cost of goods sold} - \text{Selling} \\ &\quad \text{and general administrative expenses} \end{aligned}$$

However, while this mathematical identity is true, this is not what we discover in the data. After we calculate the two factors, we form quintile portfolios of each factor and compare the individual holding rankings between the portfolio. Figure 1 displays the percentage differences in rankings for individual companies between the two portfolios. We observe that the results are not identical. As a matter of fact, there are large differences, particularly in the early period. In other words, the two mathematically equivalent approaches do not deliver the same empirical results.

Potential Biases from Data

There are numerous potential biases that may arise from data quality issues. It is important to recognize the direct effects of these data issues

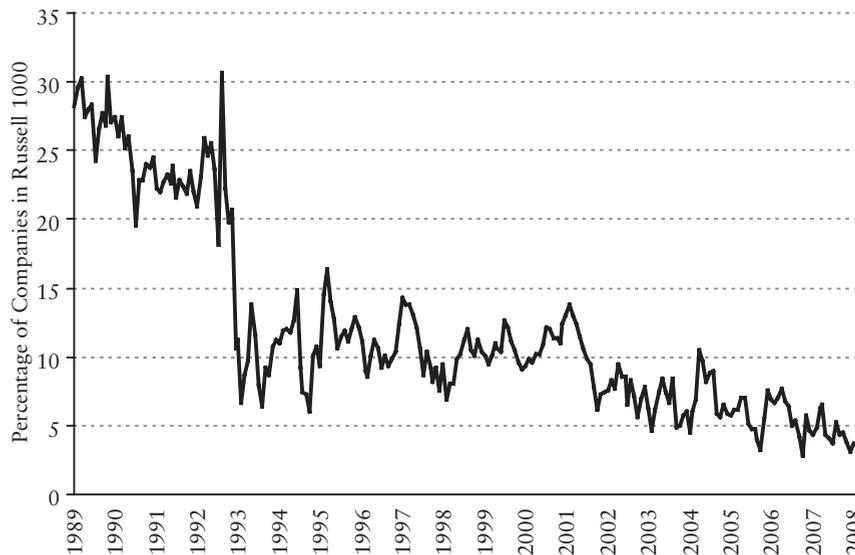

Figure 1 Percentage of Companies in Russell 1000 with Different Ranking According to the EBITDA/EV Factor

are not apparent a priori. We emphasize three important effects:¹²

1. *Effect on average stock characteristics.* When calculating cross-sectional averages of various metrics such as book-to-price or market capitalization, data issues can skew statistics and lead to incorrect inference about the population characteristics used in the study.
2. *Effect on portfolio returns.* The portfolio return implications of data issues are not always clear. For example, survivor bias results in firms being removed from the sample. Typically firms are removed from the sample for one of two reasons—mergers and acquisitions or failure. In most cases firms are acquired at a premium from the prevailing stock price. Leaving these firms out of the sample would have a downward bias on returns. In cases where companies fail, the stock price falls dramatically and removing these firms from the sample will have an upward bias on returns.
3. *Effects on estimated moments of returns.* A study by Kothari, Sabino, and Zach (2005) found that nonsurviving firms tend to be either extremely bad or extremely good performers. Survivor bias implies truncation of such extreme observations. The authors of the study show that even a small degree of such non-random truncation can have a strong impact on the sample moments of stock returns.

Dealing with Common Data Issues

Most data sets are subject to some quality issues. To work effectively, we need to be familiar with data definitions and database design. We also need to use processes to reduce the potential impact of data problems as they could cause incorrect conclusions.

The first step is to become familiar with the data standardization process vendors use to collect and process data. For example, many vendors use different templates to store data.

Specifically, the Compustat US database has one template for reporting income statement data, while the Worldscope Global database has four different templates depending on whether a firm is classified as a bank, insurance company, industrial company, or other financial company. Other questions related to standardization a user should be familiar with include:

- What are the sources of the data—publicly available financial statements, regulatory filings, newswire services, or other sources?
- Is there a uniform reporting template?
- What is the delay between publication of information and its availability in the database?
- Is the data adjusted for stock splits?
- Is history available for extinct or inactive companies?
- How is data handled for companies with multiple share classes?
- What is the process used to aggregate the data?

Understanding of the accounting principles underlying the data is critical. Here, two principles of importance are the valuation methodology and data disclosure or presentation. For the valuation, we should understand the type of cost basis used for the various accounting items. Specifically, are assets calculated using historical cost basis, fair value accounting, or another type? For accounting principles regarding disclosure and presentation, we need to know the definition of accounting terms, the format of the accounts, and the depth of detail provided.

Researchers creating factors that use financial statements should review the history of the underlying accounting principles. For example, the cash flow statement reported by companies has changed over the years. Effective for fiscal years ending July 15, 1988, Statement of Financial Accounting Standards No. 85 (SFAS No. 85) requires companies to report the Statement of Cash Flows. Prior to the adoption of that accounting standard, companies could report one

of three statements: Working Capital Statement, Cash Statement by Source and Use of Funds, or Cash Statement by Activity. Historical analysis of any factor that uses cash flow items will require adjustments to the definition of the factor to account for the different statements used by companies.

Preferably, automated processes should be used to reduce the potential impact of data problems. We start by checking the data for consistency and accuracy. We can perform time series analysis on individual factors looking at outliers and for missing data. We can use magnitude tests to compare current data items with the same items for prior periods, looking for data that are larger than a predetermined variance. When suspicious cases are identified, the cause of the error should be researched and any necessary changes made.

Methods to Adjust Factors

At first, factors consist of raw data from a database combined in an economically meaningful way. After the initial setup, a factor may be adjusted using analytical or statistical techniques to be more useful for modeling. The following three adjustments are common.

Standardization

Standardization rescales a variable while preserving its order. Typically, we choose the standardized variable to have a mean of zero and a standard deviation of one by using the transformation

$$x_i^{\text{new}} = \frac{x_i - \bar{x}}{\sigma_x}$$

where x_i is the stock's factor score, \bar{x} is the universe average, and σ_x is the universe standard deviation. There are several reasons to scale a variable in this way. First, it allows one to determine a stock's position relative to the universe average. Second, it allows better comparison across a set of factors since means and standard

deviations are the same. Third, it can be useful in combining multiple variables.

Orthogonalization

Sometimes the performance of our factor might be related to another factor. Orthogonalizing a factor for other specified factor(s) removes this relationship. We can orthogonalize by using averages or running regressions.

To orthogonalize the factor using averages according to industries or sectors, we can proceed as follows. First, for each industry we calculate the industry scores

$$s_k = \frac{\sum_{i=1}^n x_i \cdot \text{ind}_{i,k}}{\sum_{i=1}^n \text{ind}_{i,k}}$$

where x_i is a factor and $\text{ind}_{i,k}$ represent the weight of stock i in industry k . Next, we subtract the industry average of the industry scores, s_k , from each stock. We compute

$$x_i^{\text{new}} = x_i - \sum_{k \in \text{Industries}} \text{ind}_{i,k} \cdot s_k$$

where x_i^{new} is the new industry neutral factor.

We can use linear regression to orthogonalize a factor. We first determine the coefficients in the equation

$$x_i = a + b \cdot f_i + \varepsilon_i$$

where f_i is the factor to orthogonalize the factor x_i by, b is the contribution of f_i to x_i , and ε_i is the component of the factor x_i not related to f_i . ε_i is orthogonal to f_i (that is, ε_i is independent of f_i) and represents the neutralized factor

$$x_i^{\text{new}} = \varepsilon_i$$

In the same fashion, we can orthogonalize our variable relative to a set of factors by using the multivariate linear regression

$$x_i = a + \sum_j b_j \cdot f_j + \varepsilon_i$$

and then setting $x_i^{\text{new}} = \varepsilon_i$.

Often portfolio managers use a risk model to forecast risk and an alpha model to forecast returns. The interaction between factors in a risk model and an alpha model often concerns portfolio managers. One possible approach to address this concern is to orthogonalize the factors or final scores from the alpha model against the factors used in the risk model. Later in the entry, we discuss this issue in more detail.

Transformation

It is common practice to apply transformations to data used in statistical and econometric models. In particular, factors are often transformed such that the resulting series is symmetric or close to being normally distributed. Frequently used transformations include natural logarithms, exponentials, and square roots. For example, a factor such as market capitalization has a large skew because a sample of large-cap stocks typically includes mega-capitalization stocks. To reduce the influence of mega-capitalization companies, we may instead use the natural logarithm of market capitalization in a linear regression model.

Outlier Detection and Management

Outliers are observations that seem to be inconsistent with the other values in a data set. Financial data contain outliers for a number of reasons including data errors, measurement errors, or unusual events. Interpretation of data containing outliers may therefore be misleading. For example, our estimates could be biased or distorted, resulting in incorrect conclusions.

Outliers can be detected by several methods. Graphs such as boxplots, scatter plots, or histograms can be useful to visually identify them. Alternatively, there are a number of numerical techniques available. One common method is to compute the interquartile-range and then identify outliers as those values that are some multiple of the range. The interquartile-range is a

measure of dispersion and is calculated as the difference between the third and first quartiles of a sample. This measure represents the middle 50% of the data, removing the influence of outliers.

After outliers have been identified, we need to reduce their influence in our analysis. Trimming and winsorization are common procedures for this purpose. Trimming discards extreme values in the data set. This transformation requires the researcher to determine the direction (symmetric or asymmetric) and the amount of trimming to occur.

Winsorization is the process of transforming extreme values in the data. First, we calculate percentiles of the data. Next we define outliers by referencing a certain percentile ranking. For example, any data observation that is greater than the 97.5 percentile or less than the 2.5 percentile could be considered an outlier. Finally, we set all values greater or less than the reference percentile ranking to particular values. In our example, we may set all values greater than the 97.5 percentile to the 97.5 percentile value and all values less than 2.5 percentile set to the 2.5 percentile value. It is important to fully investigate the practical consequences of using either one of these procedures.

ANALYSIS OF FACTOR DATA

After constructing factors for all securities in the investable universe, each factor is analyzed individually. Presenting the time-series and cross-sectional averages of the mean, standard deviations, and key percentiles of the distribution provide useful information for understanding the behavior of the chosen factors.

Although we often rely on techniques that assume the underlying data generating process is normally distributed, or at least approximately, most financial data is not. The underlying data generating processes that embody aggregate investor behavior and characterize the financial markets are unknown and exhibit significant

uncertainty. Investor behavior is uncertain because not all investors make rational decisions or have the same goals. Analyzing the properties of data may help us better understand how uncertainty affects our choice and calibration of a model.

Below we provide some examples of the cross-sectional characteristics of various factors. For ease of exposition we use histograms to evaluate the data rather than formal statistical tests. We let particular patterns or properties of the histograms guide us in the choice of the appropriate technique to model the factor. We recommend that an intuitive exploration should be followed by a more formal statistical testing procedure. Our approach here is to analyze the entire sample, all positive values, all negative values, and zero values. Although omitted here, a thorough analysis should also include separate subsample analysis.

Example 1: EBITDA/EV

The first factor we discuss is the earnings before interest, taxes, and amortization to enterprise value (EBITDA/EV) factor. Enterprise value is calculated as the market value of the capital structure. This factor measures the price (enterprise value) investors pay to receive the cash flows (EBITDA) of a company. The economic intuition underlying this factor is that the valuation of a company's cash flow determines the attractiveness of companies to an investor.

Figure 2(A) presents a histogram of all cross-sectional values of the EBITDA/EV factor throughout the entire history of the study. The distribution is close to normal, showing there is a fairly symmetric dispersion among the valuations companies receive. Figure 2(B) shows that the distribution of all the positive values of the factor is also almost normally distributed. On the other hand, Figure 2(C) shows that the distribution of the negative values is skewed to the left. However, because there are only a small number of negative values, it is likely that they will not greatly influence our model.

Example 2: Revisions

We evaluate the cross-sectional distribution of the earnings revisions factor.¹³ The revisions factor we use is derived from sell-side analyst earnings forecasts from the IBES database. The factor is calculated as the number of analysts who revise their earnings forecast upward minus the number of downward forecasts, divided by the total number of forecasts. The economic intuition underlying this factor is that there should be a positive relation to changes in forecasts of earnings and subsequent returns.

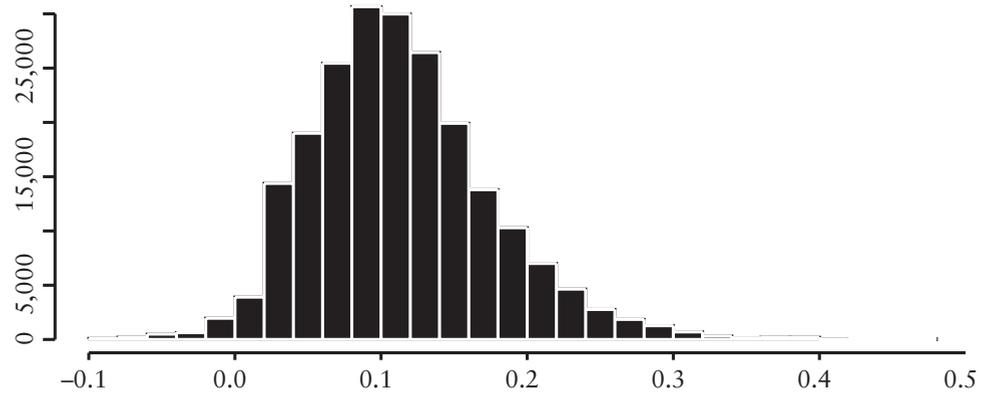

In Figure 3(A) we see that the distribution of revisions is symmetric and leptokurtic around a mean of about zero. This distribution ties with the economic intuition behind the revisions. Since business prospects of companies typically do not change from month-to-month, sell-side analysts will not revise their earnings forecast every month. Consequently, we expect and find the cross-sectional range to be peaked at zero. Figure 3(B) and (C), respectively, show there is a smaller number of both positive and negative earnings revisions and each one of these distributions are skewed.

Example 3: Share Repurchase

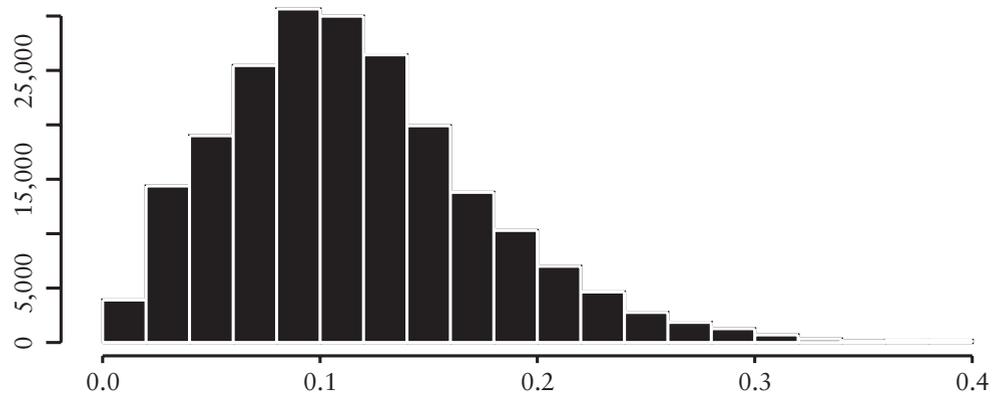

We evaluate the cross-sectional distribution of the shares repurchases factor. This factor is calculated as the difference of the current number of common shares outstanding and the number of shares outstanding 12 months ago, divided by the number of shares outstanding 12 months ago. The economic intuition underlying this factor is that share repurchase provides information to investors about future earnings and valuation of the company's stock.¹⁴ We expect there to be a positive relationship between a reduction in shares outstanding and subsequent returns.

We see in Figure 4(A) that the distribution is leptokurtic. The positive values (see Figure 4(B)) are skewed to the right and the

A. All Factor Values

B. Positive Factor Values

C. Negative Factor Values

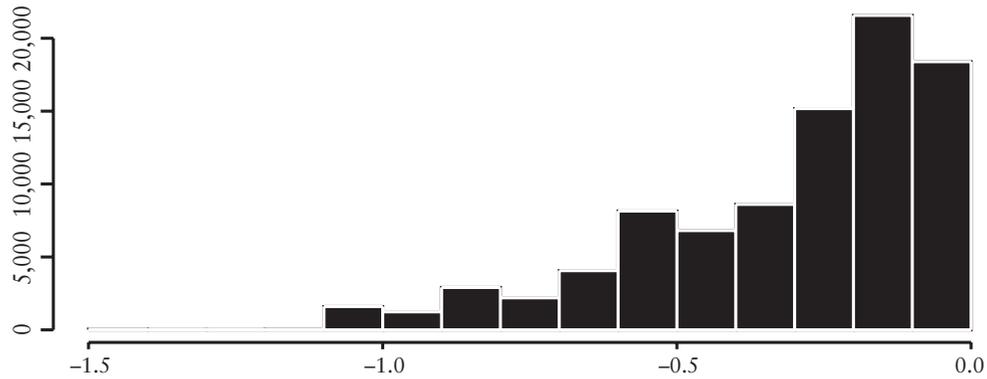

Figure 3 Histograms of the Cross-Sectional Values for the Revisions Factor

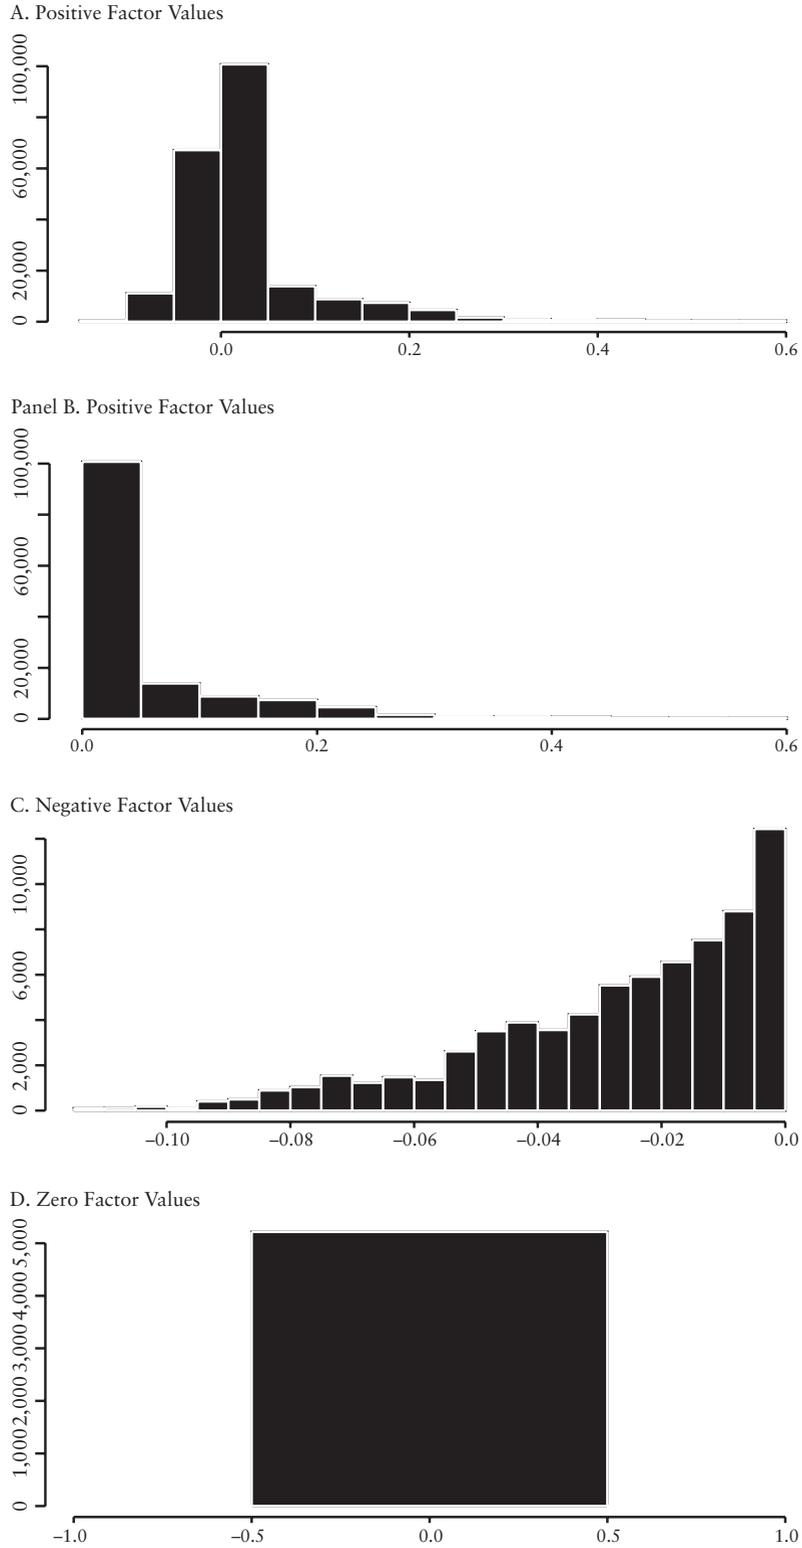

Figure 4 Histograms of the Cross-Sectional Values for the Share Repurchase Factor

negative values (see Figure 4(C)) are clustered in a small band. The economic intuition underlying share repurchases is the following. Firms with increasing share count indicate they require additional sources of cash. This need could be an early sign that the firm is experiencing higher operating risks or financial distress. We would expect these firms to have lower future returns. Firms with decreasing share count have excess cash and are returning value back to shareholders. Decreasing share count could result because management believes the shares are undervalued. As expected, we find the cross-sectional range to be peaked at zero (see Figure 4(D)) since not all firms issue or repurchase shares on a regular basis.

KEY POINTS

- A factor is a common characteristic among a group of assets. Factors should be founded on sound economic intuition, market insight, or an anomaly.
- Factors fall into three categories—macroeconomic, cross-sectional, and statistical factors.
- The main steps in the development of a factor-based trading strategy are (1) defining a trading idea or investment strategy, (2) developing factors, (3) acquiring and processing data, (4) analyzing the factors, (5) building the strategy, (6) evaluating the strategy, (7) back-testing the strategy, and (8) implementing the strategy.
- Most trading strategies are exposed to risk. The main sources of risk are fundamental risk, noise trader risk, horizon risk, model risk, implementation risk, and liquidity risk.
- Factors are often derived from company characteristics and metrics, and market data. Examples of company characteristics and metrics include valuation ratios, operating efficiency ratios, profitability ratios, and solvency ratios. Example of useful market data include analysts forecasts, prices and returns, and trading volume.
- High-quality data are critical to the success of a trading strategy. Model output is only as good as the data used to calibrate it.
- Some common data problems and biases are backfilling and restatements of data, missing data, inconsistently reported data, and survivorship and look-ahead biases.
- The ability to detect and adjust outliers is crucial to a quantitative investment process.
- Common methods used for adjusting data are standardization, orthogonalization, transformation, trimming, and winsorization.
- The statistical properties of factors need to be carefully analyzed. Basic statistical measures include the time-series and cross-sectional averages of the mean, standard deviations, and key percentiles.

Abstract: Quantitative asset managers construct and apply models that can be used for dynamic multifactor trading strategies. These models incorporate a number of common institutional constraints such as turnover, transaction costs, sector, and tracking error. Approaches for the evaluation of return premiums and risk characteristics to factors include portfolio sorts, factor models, factor portfolios, and information coefficients. Several techniques are used to combine several factors into a single model—a trading strategy. These techniques include data driven, factor model, heuristic, and optimization approaches.

In the construction of factor models, factors are constructed from company characteristics and market data. In this entry, we explain and illustrate how to include multiple factors with the purpose of developing a dynamic multifactor trading strategy that incorporates a number of common institutional constraints such as turnover, transaction costs, sector, and *tracking error*. For this purpose, we use a combination of growth, value, quality, and momentum factors. For the purpose of our illustration, our universe of stocks is the Russell 1000 from December 1989 to December 2008, and we construct our factors by using the Compustat

Point-In-Time and IBES databases. A complete list of the factors and data sets used is provided in the appendix.

We begin by reviewing several approaches for the evaluation of return premiums and risk characteristics to factors, including portfolio sorts, factor models, factor portfolios, and information coefficients. We then turn to techniques that are used to combine several factors into a single model—a trading strategy. In particular, we discuss the data driven, factor model, heuristic, and optimization approaches. It is critical to perform out-of-sample backtests of a trading strategy to understand its performance

and risk characteristics. We cover the split-sample and recursive out-of-sample tests.

Throughout this entry, we provide a series of examples, including backtests of a multifactor trading strategy. The purpose of these examples is not to attempt to provide a profitable trading strategy, but rather to illustrate the process a financial modeler may follow when performing research. We emphasize that the factors that we use are well known and have for years been exploited by industry practitioners. We think that the value added of these examples is in the concrete illustration of the research and development process of a factor-based trading model.

CROSS-SECTIONAL METHODS FOR EVALUATION OF FACTOR PREMIUMS

There are several approaches used for the evaluation of return premiums and risk characteristics to factors. In this section, we discuss the four most commonly used approaches: portfolio sorts, factor models, factor portfolios, and information coefficients. We examine the methodology of each approach and summarize its advantages and disadvantages.

In practice, to determine the right approach for a given situation there are several issues to consider. One determinant is the structure of the financial data. A second determinant is the economic intuition underlying the factor. For example, sometimes we are looking for a monotonic relationship between returns and factors while at other times we care only about extreme values. A third determinant is whether the underlying assumptions of each approach are valid for the data-generating process at hand.

Portfolio Sorts

In the asset pricing literature, the use of *portfolio sorts* can be traced back to the earliest tests of the capital asset pricing model (CAPM). The goal of this particular test is to determine whether a

factor earns a systematic premium. The portfolios are constructed by grouping together securities with similar characteristics (factors). For example, we can group stocks by market capitalization into 10 portfolios—from smallest to largest—such that each portfolio contains stocks with similar market capitalization. The next step is to calculate and evaluate the returns of these portfolios.

The return for each portfolio is calculated by equally weighting the individual stock returns. The portfolios provide a representation of how returns vary across the different values of a factor. By studying the return behavior of the factor portfolios, we may assess the return and risk profile of the factor. In some cases, we may identify a monotonic relationship of the returns across the portfolios. In other cases, we may identify a large difference in returns between the extreme portfolios. In still other cases, there may be no relationship between the portfolio returns. Overall, the return behavior of the portfolios will help us conclude whether there is a premium associated with a factor and describe its properties.

One application of the portfolio sort is the construction of a *factor mimicking portfolio* (FMP). An FMP is a long-short portfolio that goes long stocks with high values of a factor and short stocks with low values of a factor, in equal dollar amounts. An FMP is a zero-cost factor trading strategy.

Portfolio sorts have become so widespread among practitioners and academics alike that they elicit few econometric queries, and often no econometric justification for the technique is offered. While a detailed discussion of these topics is beyond the scope of this book, we would like to point out that asset pricing tests used on sorted portfolios may exhibit a bias that favors rejecting the asset pricing model under consideration.¹

The construction of portfolios sorted on a factor is straightforward:

- Choose an appropriate sorting methodology.
- Sort the assets according to the factor.

- Group the sorted assets into N portfolios (usually $N = 5$, or $N = 10$).
- Compute average returns (and other statistics) of the assets in each portfolio over subsequent periods.

The standard statistical testing procedure for portfolio sorts is to use a Student's t -test to evaluate the significance of the mean return differential between the portfolios of stocks with the highest and lowest values of the factor.

Choosing the Sorting Methodology

The sorting methodology should be consistent with the characteristics of the distribution of the factor and the economic motivation underlying its premium. We list six ways to sort factors:

Method 1

- Sort stocks with factor values from the highest to lowest.

Method 2

- Sort stocks with factor values from the lowest to highest.

Method 3

- First allocate stocks with zero factor values into the bottom portfolio.
- Sort the remaining stocks with nonzero factor values into the remaining portfolios.

For example, the dividend yield factor would be suitable for this sorting approach. This approach aligns the factor's distributional characteristics of dividend and nondividend-paying stocks with the economic rationale. Typically, nondividend-paying stocks maintain characteristics that are different from dividend paying stocks. So we group nondividend-paying stocks into one portfolio. The remaining stocks are then grouped into portfolios depending on the size of their nonzero dividend yields. We differentiate among stocks with dividend yield because of two reasons: (1) the size of the dividend yield is related to the maturity of the company, and (2) some investors prefer to receive their investment return as dividends.

Method 4

- Allocate stocks with zero factor values into the middle portfolio.
- Sort stocks with positive factor values into the remaining higher portfolios (greater than the middle portfolio).
- Sort stocks with negative factor values into the remaining lower portfolios (less than the middle portfolio).

Method 5

- Sort stocks into partitions.
- Rank assets within each partition.
- Combine assets with the same ranking from the different partitions into portfolios.

An example will clarify this procedure. Suppose we want to rank stocks according to earnings growth on a sector-neutral basis. First, we separate stocks into groups corresponding to their sector. Within each sector, we rank the stocks according to their earnings growth. Lastly, we group all stocks with the same rankings of earnings growth into the final portfolio. This process ensures that each portfolio will contain an equal number of stocks from every sector, thereby the resulting portfolios are sector neutral.

Method 6

- Separate all the stocks with negative factor values. Split the group of stocks with negative values into two portfolios using the median value as the break point.
- Allocate stocks with zero factor values into one portfolio.
- Sort the remaining stocks with nonzero factor values into portfolios based on their factor values.

An example of method 6 is the share repurchase factor. We are interested in the extreme positive and negative values of this factor. As we see in Figure 5(A), the distribution of these factors is leptokurtic with the positive values skewed to the right and the negative values clustered in a small range. By choosing method 6 to sort this variable, we can distinguish

between those values we view as extreme. The negative values are clustered so we want to distinguish among the magnitudes of those values. We accomplish this because our sorting method separates the negative values by the median of the negative values. The largest negative values form the extreme negative portfolio. The positive values are skewed to the right, so we want to differentiate between the larger and smaller positive values. When implementing portfolio method 6, we would also separate the zero values from the positive values.

The portfolio sort methodology has several advantages. The approach is easy to implement and can easily handle stocks that drop out or enter into the sample. The resulting portfolios diversify away idiosyncratic risk of individual assets and provide a way of assessing how average returns differ across different magnitudes of a factor.

The portfolio sort methodology has several disadvantages. The resulting portfolios may be exposed to different risks beyond the factor the portfolio was sorted on. In those instances, it is difficult to know which risk characteristics have an impact on the portfolio returns. Because portfolio sorts are nonparametric, they do not give insight as to the functional form of the relation between the average portfolio returns and the factor.

Next we provide three examples to illustrate how the economic intuition of the factor and cross-sectional statistics can help determine the sorting methodology.

Example 1: Portfolio Sorts Based on the EBITDA/EV Factor

Panel A of Figure 1 contains the cross-sectional distribution of the EBITDA/EV factor. This distribution is approximately normally distributed

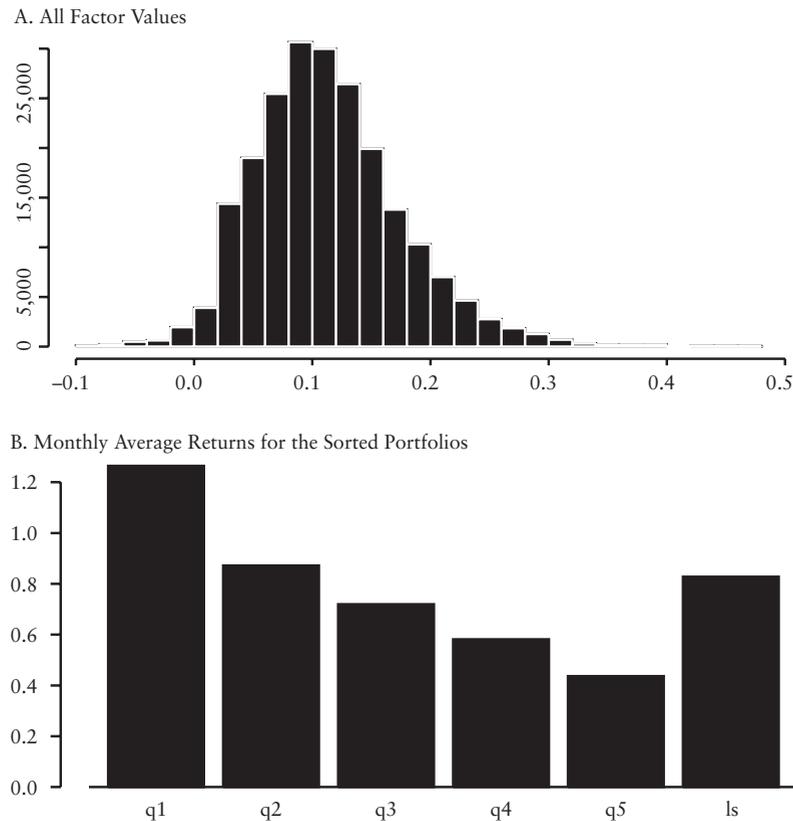

Figure 1 Portfolio Sorts Based on the EBITDA/EV Factor

around a mean of 0.1, with a slight right skew. We use method 1 to sort the variables into five portfolios (denoted by q_1, \dots, q_5) because this sorting method aligns the cross-sectional distribution of factor returns with our economic intuition that there is a linear relationship between the factor and subsequent return. In Figure 1(B), we see that there is a large difference between the equally weighted monthly returns of portfolio 1 (q_1) and portfolio 5 (q_5). Therefore, a trading strategy (denoted by ls in the graph) that goes long portfolio 1 and short portfolio 5 appears to produce abnormal returns.

Example 2: Portfolio Sorts Based on the Revisions Factor

In Figure 2(A), we see that the distribution of earnings revisions is leptokurtic around a mean of about zero, with the remaining val-

ues symmetrically distributed around the peak. The pattern in this cross-sectional distribution provides insight on how we should sort this factor. We use method 3 to sort the variables into five portfolios. The firms with no change in revisions we allocate to the middle portfolio (portfolio 3). The stocks with positive revisions we sort into portfolios 1 and 2, according to the size of the revisions—while we sort stocks with negative revisions into portfolios 4 and 5, according to the size of the revisions. In Figure 2(B), we see there is a relationship between the portfolios and subsequent monthly returns. The positive relationship between revisions and subsequent returns agrees with the factor’s underlying economic intuition: We expect that firms with improving earnings should outperform. The trading strategy that goes long portfolio 1 and short portfolio 5 (denoted by

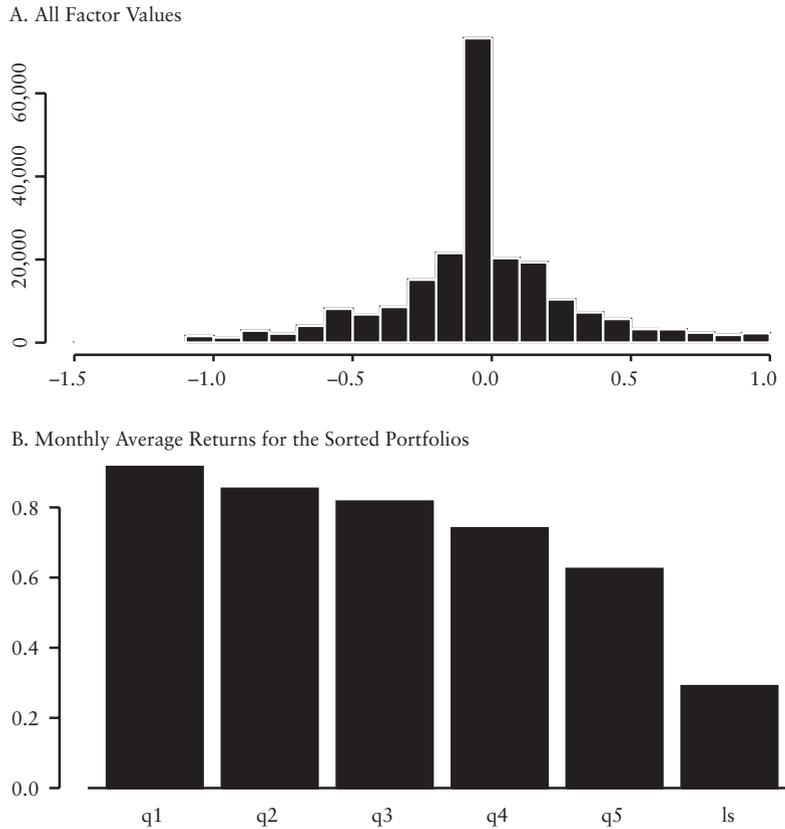

Figure 2 The Revisions Factor

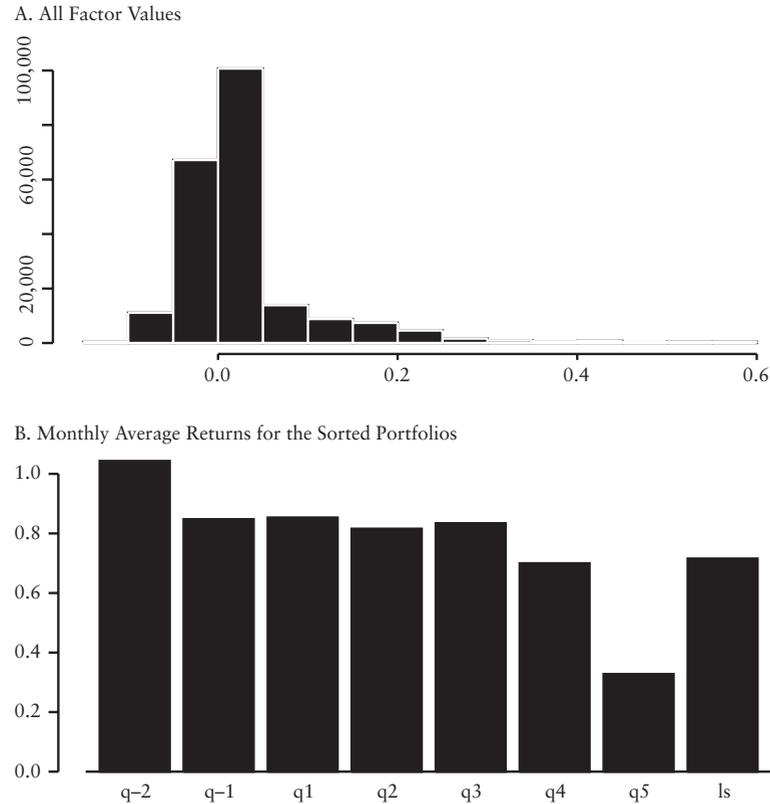

Figure 3 The Share Repurchase Factor

ls in the graph) appears to produce abnormal returns.

Example 3: Portfolio Sorts Based on the Share Repurchase Factor

In Figure 3(A), we see the distribution of share repurchase is asymmetric and leptokurtic around a mean of zero. The pattern in this cross-sectional distribution provides insight on how we should sort this factor. We use method 6 to sort the variables into seven portfolios. We group stocks with positive revisions into portfolios 1 through 5 (denoted by q_1, \dots, q_5 in the graph) according to the magnitude of the share repurchase factor. We allocate stocks with negative repurchases into portfolios q-2 and q-1 where the median of the negative values determines their membership. We split the negative numbers because we are interested in large changes in the shares outstanding. In Fig-

ure 3(B), unlike the other previous factors, we see that there is not a linear relationship between the portfolios. However, there is a large difference in return between the extreme portfolios (denoted by ls in the graph). This large difference agrees with the economic intuition of this factor. Changes in the number of shares outstanding are a potential signal for the future value and prospects of a firm. On the one hand, a large increase in shares outstanding may signal to investors (1) the need for additional cash because of financial distress, or (2) that the firm may be overvalued. On the other hand, a large decrease in the number of shares outstanding may indicate that management believes the shares are undervalued. Finally, small changes in shares outstanding, positive or negative, typically do not have an impact on stock price and therefore are not significant.

Information Ratios for Portfolio Sorts

The information ratio (IR) is a statistic for summarizing the risk-adjusted performance of an investment strategy. It is defined as the ratio of the average excess return to the standard deviation of return. For actively managed equity long portfolios, the IR measures the risk-adjusted value a portfolio manager is adding relative to a benchmark.² IR can also be used to capture the risk-adjusted performance of long-short portfolios from portfolio sorts. When comparing portfolios built using different factors, the IR is an effective measure for differentiating the performance between the strategies.

New Research on Portfolio Sorts

As we mentioned earlier in this section, the standard statistical testing procedure for portfolio sorts is to use a Student's t -test to evaluate the mean return differential between the two portfolios containing stocks with the highest and lowest values of the sorting factor. However, evaluating the return between these two portfolios ignores important information about the overall pattern of returns among the remaining portfolios.

Recent research by Patton and Timmermann (2009) provides new analytical techniques to increase the robustness of inference from portfolio sorts. The technique tests for the presence of a monotonic relationship between the portfolios and their expected returns. To find out if there is a systematic relationship between a factor and portfolio returns, they use the monotonic relation (MR) test to reveal whether the null hypothesis of no systematic relationship can be rejected in favor of a monotonic relationship predicted by economic theory. By MR it is meant that the expected returns of a factor should rise or decline monotonically in one direction as one goes from one portfolio to another. Moreover, Patton and Timmermann develop separate tests to determine the direction of deviations in support of or against the theory.

The authors emphasize several advantages in using this approach. The test is nonparametric and applicable to other cases of portfolios such as two-way and three-way sorts. This test is easy to implement via bootstrap methods. Furthermore, this test does not require specifying the functional form (e.g., linear) in relating the sorting variable to expected returns.

FACTOR MODELS

Classical financial theory states that the average return of a stock is the payoff to investors for taking on risk. One way of expressing this risk-reward relationship is through a factor model. A factor model can be used to decompose the returns of a security into factor-specific and asset-specific returns

$$r_{i,t} = \alpha_i + \beta_{i,1}f_{1,t} + \dots + \beta_{i,K}f_{K,t} + \varepsilon_{i,t}$$

where $\beta_{i,1}, \beta_{i,2}, \dots, \beta_{i,K}$ are the factor exposures of stock i , $f_{1,t}, f_{2,t}, \dots, f_{K,t}$ are the factor returns, α_i is the average abnormal return of stock i , and $\varepsilon_{i,t}$ is the residual.

This factor model specification is contemporaneous, that is, both left- and right-hand side variables (returns and factors) have the same time subscript, t . For trading strategies one generally applies a forecasting specification where the time subscript of the return and the factors are $t+h$ ($h \geq 1$) and t , respectively. In this case, the econometric specification becomes

$$r_{i,t+h} = \alpha_i + \beta_{i,1}f_{1,t} + \dots + \beta_{i,K}f_{K,t} + \varepsilon_{i,t+h}$$

How do we interpret a trading strategy based on a factor model? The explanatory variables represent different factors that forecast security returns, and each factor has an associated factor premium. Therefore, future security returns are proportional to the stock's exposure to the factor premium

$$E(r_{i,t+h} | f_{1,t}, \dots, f_{K,t}) = \alpha_i + \beta_i' \mathbf{f}_t$$

and the variance of future stock return is given by

$$\text{Var}(r_{i,t+b} | f_{1,t}, \dots, f_{K,t}) = \beta_i' E(\mathbf{f}_t \mathbf{f}_t') \beta_i$$

where and $\beta_i = (\beta_{i,1}, \beta_{i,2}, \dots, \beta_{i,k})'$ and $\mathbf{f}_t = (f_{1,t}, f_{2,t}, \dots, f_{K,t})'$.

In the next section we discuss some specific econometric issues regarding cross-sectional regressions and factor models.

Econometric Considerations for Cross-Sectional Factor Models

In cross-sectional regressions, where the dependent variable³ is a stock's return and the independent variables are factors, inference problems may arise that are the result of violations of classical linear regression theory. The three most common problems are measurement problems, common variations in residuals, and multicollinearity.

Measurement Problems

Some factors are not explicitly given, but need to be estimated. These factors are estimated with an error. This error can have an impact on the inference from a factor model. This problem is commonly referred to as the "errors in variables problem." For example, a factor that is comprised of a stock's beta is estimated with an error because beta is determined from a regression of stock excess returns on the excess returns of a market index. While beyond the scope of this entry, several approaches have been suggested to deal with this problem:⁴

Common Variation in Residuals

The residuals from a regression often contain a source of common variation. Sources of common variation in the residuals are heteroskedasticity and serial correlation.⁵ We note that when the form of heteroskedasticity and serial correlation is known, we can apply generalized least squares (GLS). If the form is not known, it has

to be estimated, for example as part of feasible generalized least squares (FGLS). We summarize some additional possibilities next.

Heteroskedasticity occurs when the variance of the residual differs across observations and affects the statistical inference in a linear regression. In particular, the estimated standard errors will be underestimated and the t -statistics will therefore be inflated. Ignoring heteroskedasticity may lead the researcher to find significant relationships where none actually exist. Several procedures have been developed to calculate standard errors that are robust to heteroskedasticity, also known as heteroskedasticity-consistent standard errors.

Serial correlation occurs when residuals terms in a linear regression are correlated, violating the assumptions of regression theory. If the serial correlation is positive, then the standard errors are underestimated and the t -statistics will be inflated. Cochrane (2005) suggests that the errors in cross-sectional regressions using financial data are often off by a factor of 10. Procedures are available to correct for serial correlation when calculating standard errors.

When the residuals from a regression are both heteroskedastic and serially correlated, procedures are available to correct them. One commonly used procedure is the one proposed by Newey and West (1987) referred to as the "Newey-West corrections," and its extension by Andrews (1991).

Petersen (2009) provides guidance on choosing the appropriate method to use for correctly calculating standard errors in panel data regressions when the residuals are correlated. He shows the relative accuracy of the different methods depends on the structure of the data. In the presence of firm effects, where the residuals of a given firm may be correlated across years, ordinary least squares (OLS), Newey-West (modified for panel data sets), or Fama-MacBeth,⁶ corrected for first-order autocorrelation, all produce biased standard errors. To correct for this, Petersen recommends using standard errors clustered by firms. If the firm

effect is permanent, the fixed effects and random effects models produce unbiased standard errors. In the presence of time effects, where the residuals of a given period may be correlated across different firms (cross-sectional dependence), Fama-MacBeth produces unbiased standard errors. Furthermore, standard errors clustered by time are unbiased when there are a sufficient number of clusters. To select the correct approach he recommends determining the form of dependence in the data and comparing the results from several methods.

Gow, Ormazabal, and Taylor (2009) evaluate empirical methods used in accounting research to correct for cross-sectional and time-series dependence. They review each of the methods, including several methods from the accounting literature that have not previously been formally evaluated, and discuss when each method produces valid inferences.

Multicollinearity

Multicollinearity occurs when two or more independent variables are highly correlated. We may encounter several problems when this happens. First, it is difficult to determine which factors influence the dependent variable. Second, the individual p values can be misleading—a p value can be high even if the variable is important. Third, the confidence intervals for the regression coefficients will be wide. They may even include zero. This implies that we cannot determine whether an increase in the independent variable is associated with an increase—or a decrease—in the dependent variable. There is no formal solution based on theory to correct for multicollinearity. The best way to correct for multicollinearity is by removing one or more of the correlated independent variables. It can also be reduced by increasing the sample size.

Fama-MacBeth Regression

To address the inference problem caused by the correlation of the residuals, Fama and MacBeth (1973) proposed the following methodol-

ogy for estimating cross-sectional regressions of returns on factors. For notational simplicity, we describe the procedure for one factor. The multifactor generalization is straightforward.

First, for each point in time t we perform a cross-sectional regression:

$$r_{i,t} = \beta_{i,t} f_t + \varepsilon_{i,t}, \quad i = 1, 2, \dots, N$$

In the academic literature, the regressions are typically performed using monthly or quarterly data, but the procedure could be used at any frequency.

The mean and standard errors of the time series of slopes and residuals are evaluated to determine the significance of the cross-sectional regression. We estimate f and ε_i as the average of their cross-sectional estimates, therefore,

$$\hat{f} = \frac{1}{T} \sum_{t=1}^T \hat{f}_t, \quad \hat{\varepsilon}_i = \frac{1}{T} \sum_{t=1}^T \hat{\varepsilon}_{i,t}$$

The variations in the estimates determine the standard error and capture the effects of residual correlation without actually estimating the correlations.⁷ We use the standard deviations of the cross-sectional regression estimates to calculate the sampling errors for these estimates

$$\sigma_{\hat{f}}^2 = \frac{1}{T^2} \sum_{t=1}^T (\hat{f}_t - \hat{f})^2, \quad \sigma_{\hat{\varepsilon}_i}^2 = \frac{1}{T^2} \sum_{t=1}^T (\hat{\varepsilon}_{i,t} - \hat{\varepsilon}_i)^2$$

Cochrane (2005) provides a detailed analysis of this procedure and compares it to cross-sectional OLS and pooled time-series cross-sectional OLS. He shows that when the factors do not vary over time and the residuals are cross-sectionally correlated, but not correlated over time, then these procedures are all equivalent.

Information Coefficients

To determine the forecast ability of a model, practitioners commonly use a statistic called the *information coefficient* (IC). The IC is a linear statistic that measures the cross-sectional

correlation between a factor and its subsequent realized return:⁸

$$IC_{t,t+k} = \text{corr}(\mathbf{f}_t, \mathbf{r}_{t,t+k})$$

where \mathbf{f}_t is a vector of cross sectional factor values at time t and $\mathbf{r}_{t,t+k}$ is a vector of returns over the time period t to $t+k$.

Just like the standard correlation coefficient, the values of the IC range from -1 to $+1$. A positive IC indicates a positive relation between the factor and return. A negative IC indicates a negative relation between the factor and return. ICs are usually calculated over an interval, for example, daily or monthly. We can evaluate how a factor has performed by examining the time series behavior of the ICs. Looking at the mean IC tells how predictive the factor has been over time.

An alternate specification of this measure is to make \mathbf{f}_t the rank of a cross-sectional factor. This calculation is similar to the Spearman rank coefficient. By using the rank of the factor, we focus on the ordering of the factor instead of its value. Ranking the factor value reduces the undue influence of outliers and reduces the influence of variables with unequal variances. For the same reasons, we may also choose to rank the returns instead of using their numerical value.

Sorensen, Qian, and Hua (2007) present a framework for factor analysis based on ICs. Their measure of IC is the correlation between the factor ranks, where the ranks are the normalized z-score of the factor,⁹ and subsequent return. Intuitively, this IC calculation measures the return associated with a one standard deviation exposure to the factor. Their IC calculation is further refined by risk adjusting the value. To risk adjust, the authors remove systematic risks from the IC and accommodate the IC for specific risk. By removing these risks, Qian and Hua (2004) show that the resulting ICs provide a more accurate measure of the return forecasting ability of the factor.

The subsequent realized returns to a factor typically vary over different time horizons. For example, the return to a factor based on

price reversal is realized over short horizons, while valuation metrics such as EBITDA/EV are realized over longer periods. It therefore makes sense to calculate multiple ICs for a set of factor forecasts whereby each calculation varies the horizon over which the returns are measured.

The IC methodology has many of the same advantages as regression models. The procedure is easy to implement. The functional relationship between factor and subsequent returns is known (linear).

ICs can also be used to assess the risk of factors and trading strategies. The standard deviation of the time series (with respect to t) of ICs for a particular factor ($\text{std}(IC_{t,t+k})$) can be interpreted as the strategy risk of a factor. Examining the time series behavior of $\text{std}(IC_{t,t+k})$ over different time periods may give a better understanding of how often a particular factor may fail. Qian and Hua show that $\text{std}(IC_{t,t+k})$ can be used to more effectively understand the active risk of investment portfolios. Their research demonstrates that ex post tracking error often exceeds the ex ante tracking provided by risk models. The difference in tracking error occurs because tracking error is a function of both ex ante tracking error from a risk model and the variability of information coefficients, $\text{std}(IC_{t,t+k})$. They define the expected tracking error as

$$\sigma_{TE} = \text{std}(IC_{t,t+k})\sqrt{N}\sigma_{\text{model}}\text{dis}(\mathbf{R}_t)$$

where N is the number of stocks in the universe (breadth), σ_{model} is the risk model tracking error, and $\text{dis}(\mathbf{R}_t)$ is dispersion of returns¹⁰ defined by

$$\text{dis}(\mathbf{R}_t) = \text{std}(r_{1,t}, r_{2,t}, \dots, r_{N,t})$$

Example: Information Coefficients

Figure 4 displays the time-varying behavior of ICs for each one of the factors EBITDA/EV, growth of fiscal year 1 and fiscal year 2 earnings estimates, revisions, and momentum. The

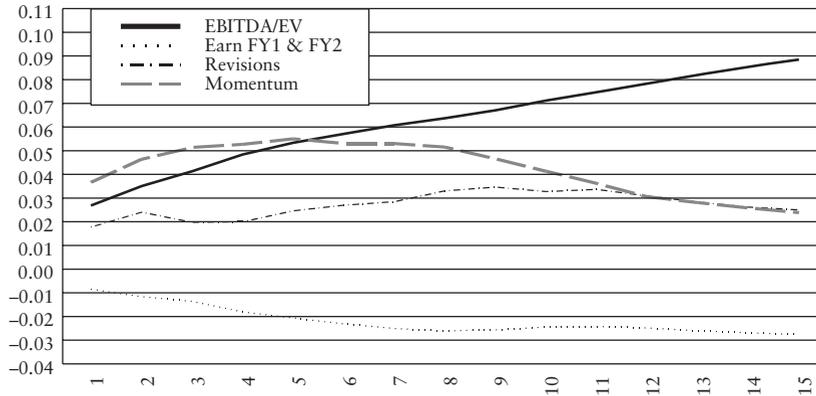

Figure 4 Information Coefficients over Various Horizons for EBITDA/EV, Growth of Fiscal Year 1 and Fiscal Year 2 Earnings Estimates, Revisions, and Momentum Factors

graph shows the time series average of information coefficients:

$$\overline{IC}_k = \text{mean}(IC_{t,t+k})$$

The graph depicts the information horizons for each factor, showing how subsequent return is realized over time. The vertical axis shows the size of the average information coefficient \overline{IC}_k for $k = 1, 2, \dots, 15$.

Specifically, the EBITDA/EV factor starts at almost 0.03 and monotonically increases as the investment horizon lengthens from one month to 15 months. At 15 months, the EBITDA/EV factor has an IC of 0.09, the highest value among all the factors presented in the graph. This relationship suggests that the EBITDA/EV factor earns higher returns as the holding period lengthens.

The other ICs of the factors in the graph are also interesting. The growth of fiscal year 1 and fiscal year 2 earnings estimates factor is defined as the growth in current fiscal year (fy1) earnings estimates to the next fiscal year (fy2) earnings estimates provided by sell-side analysts.¹¹ We call the growth of fiscal year 1 and fiscal year 2 earnings estimates factor the *earnings growth factor* throughout the remainder of the entry. The IC is negative and decreases as the investment horizon lengthens. The momentum factor starts with a positive IC of 0.02

and increases to approximately 0.055 in the fifth month. After the fifth month, the IC decreases. The revisions factor starts with a positive IC and increases slightly until approximately the eleventh month at which time the factor begins to decay.

Looking at the overall patterns in the graph, we see that the return realization pattern to different factors varies. One notable observation is that the returns to factors don't necessarily decay but sometimes grow with the holding period. Understanding the multiperiod effects of each factor is important when we want to combine several factors. This information may influence how one builds a model. For example, we can explicitly incorporate this information about information horizons into our model by using a function that describes the decay or growth of a factor as a parameter to be calibrated. Implicitly, we could incorporate this information by changing the holding period for a security traded for our trading strategy. Specifically, Sneddon (2008) discusses an example that combines one signal that has short-range predictive power with another that has long-range power. Incorporating this information about the information horizon often improves the return potential of a model. Kolm (2010) describes a general multiperiod model that combines information decay, market impact costs, and real world constraints.

Factor Portfolios

Factor portfolios are constructed to measure the information content of a factor. The objective is to mimic the return behavior of a factor and minimize the residual risk. Similar to portfolio sorts, we evaluate the behavior of these factor portfolios to determine whether a factor earns a systematic premium.

Typically, a factor portfolio has a unit exposure to a factor and zero exposure to other factors. Construction of factor portfolios requires holding both long and short positions. We can also build a factor portfolio that has exposure to multiple attributes, such as beta, sectors, or other characteristics. For example, we could build a portfolio that has a unit exposure to book-to-price and small size stocks. Portfolios with exposures to multiple factors provide the opportunity to analyze the interaction of different factors.

A Factor Model Approach

By using a multifactor model, we can build factor portfolios that control for different risks.¹² We decompose return and risk at a point in time into a systematic and specific component using the regression:

$$\mathbf{r} = \mathbf{X}\mathbf{b} + \mathbf{u}$$

where \mathbf{r} is an N vector of excess returns of the stocks considered, \mathbf{X} is an N by K matrix of factor loadings, \mathbf{b} is a K vector of factor returns, and \mathbf{u} is an N vector of firm specific returns (residual returns). Here, we assume that factor returns are uncorrelated with the firm specific return. Further assuming that firm specific returns of different companies are uncorrelated, the N by N covariance matrix of stock returns \mathbf{V} is given by

$$\mathbf{V} = \mathbf{X}\mathbf{F}\mathbf{X}' + \mathbf{\Delta}$$

where \mathbf{F} is the K by K factor return covariance matrix and $\mathbf{\Delta}$ is the N by N diagonal matrix of variances of the specific returns.

We can use the Fama-MacBeth procedure discussed earlier to estimate the factor returns over time. Each month, we perform a GLS regression to obtain

$$\mathbf{b} = (\mathbf{X}'\mathbf{\Delta}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Delta}^{-1}\mathbf{r}$$

OLS would give us an unbiased estimate, but since the residuals are heteroskedastic the GLS methodology is preferred and will deliver a more efficient estimate. The resulting holdings for each factor portfolio are given by the rows of $(\mathbf{X}'\mathbf{\Delta}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Delta}^{-1}$.

An Optimization-Based Approach

A second approach to build factor portfolios uses mean-variance optimization. Using optimization techniques provides a flexible approach for implementing additional objectives and constraints.¹³

Using the notation from the previous subsection, we denote by \mathbf{X} the set of factors. We would like to construct a portfolio that has maximum exposure to one target factor from \mathbf{X} (the alpha factor), zero exposure to all other factors, and minimum portfolio risk. Let us denote the alpha factor by \mathbf{X}_α and all the remaining ones by \mathbf{X}_σ . Then the resulting optimization problem takes the form

$$\begin{aligned} \max_{\mathbf{w}} \quad & \left\{ \mathbf{w}'\mathbf{X}_\alpha - \frac{1}{2}\lambda\mathbf{w}'\mathbf{V}\mathbf{w} \right\} \\ \text{s.t.} \quad & \mathbf{w}'\mathbf{X}_\sigma = 0 \end{aligned}$$

The analytical solution to this optimization problem is given by

$$h^* = \frac{1}{\lambda}\mathbf{V}^{-1}[\mathbf{I} - \mathbf{X}_\sigma(\mathbf{X}'_\sigma\mathbf{V}^{-1}\mathbf{X}_\sigma)^{-1}\mathbf{X}'_\sigma\mathbf{V}^{-1}]\mathbf{X}_\alpha$$

We may want to add additional constraints to the problem. Constraints are added to make factor portfolios easier to implement and meet additional objectives. Some common constraints include limitations on turnover, transaction costs, the number of assets, and liquidity preferences. These constraints¹⁴ are typically implemented as linear inequality constraints. When no analytical solution is available to solve the

optimization with linear inequality constraints, we have to resort to quadratic programming (QP).¹⁵

PERFORMANCE EVALUATION OF FACTORS

Analyzing the performance of different factors is an important part of the development of a *factor-based trading strategy*. A researcher may construct and analyze over a hundred different factors, so a process to evaluate and compare these factors is needed. Most often this process starts by trying to understand the time-series properties of each factor in isolation and then study how they interact with each other.

To give a basic idea of how this process may be performed, we use the five factors introduced earlier in this entry: EBITDA/EV, revisions, share repurchase, momentum, and earnings growth. These are a subset of the factors that we use in the factor trading strategy model discussed later in the entry. We choose a limited number of factors for ease of exposition. In particular, we emphasize those factors that possess more interesting empirical characteristics.

Figure 5(A) presents summary statistics of monthly returns of long-short portfolios con-

structed from these factors. We observe that the average monthly return ranges from -0.05% for the earnings growth to 0.90% for the momentum factor. The t -statistics for the mean return are significant at the 95% level for the EBITDA/EV, share repurchase, and momentum factors. The monthly volatility ranges from 3.77% for the revisions factor to 7.13% for the momentum factor. In other words, the return and risk characteristics among factors vary significantly. We note that the greatest monthly drawdown has been large to very large for all of the factors, implying significant downside risk. Overall, the results suggest that there is a systematic premium associated with the EBITDA/EV, share repurchase, and momentum factors.

Let pctPos and pctNeg denote the fraction of positive and negative returns over time, respectively. These measures offer another way of interpreting the strength and consistency of the returns to a factor. For example, EBITDA/EV and momentum have t -statistics of 2.16 and 1.90, respectively, indicating that the former is stronger. However, pctPos (pctNeg) are 0.55 versus 0.61 (0.45 versus 0.39) showing that positive returns to momentum occur more frequently. This may provide reassurance of the

Figure 5 Results from Portfolio Sorts

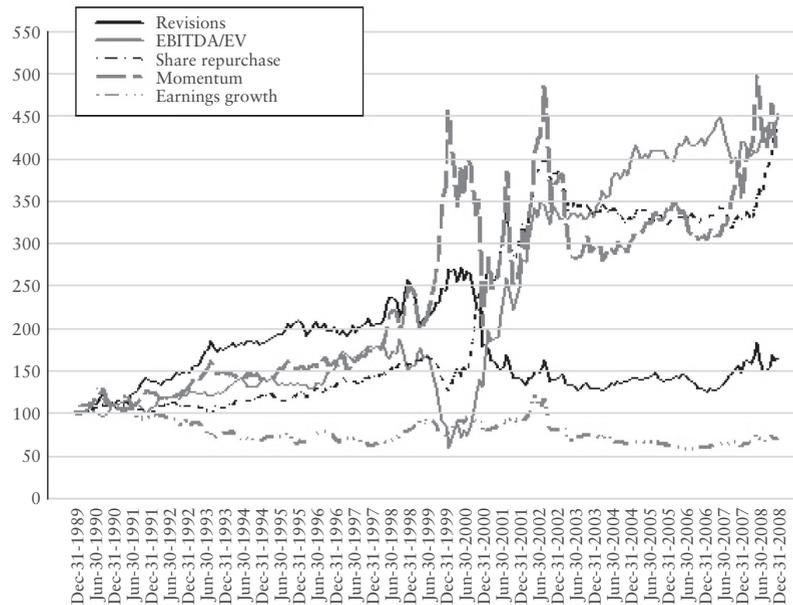

Figure 6 Cumulative Returns of Long-Short Portfolios

usefulness of the momentum factor, despite the fact that its t -statistic is below the 95% level.

Figure 5(B) presents unconditional correlation coefficients of monthly returns for long-short portfolios. The comovement of factor returns varies among the factors. The lowest correlation is -0.28 between EBITDA/EV and revisions. The highest correlation is 0.79 between momentum and revisions. In addition, we observe that the correlation between revisions and share repurchase, and between EBITDA/EV and earnings growth are close to zero. The broad range of correlations provides evidence that combining uncorrelated factors could produce a successful strategy.

Figure 6 presents the cumulative returns for the long-short portfolios. The returns of the long-short factor portfolios experience substantial volatility. We highlight the following patterns of cumulative returns for the different factors:

- The cumulative return of the revisions factor is positive in the early periods (12/1989 to 6/1998). While it is volatile, its cumulative return is higher in the next period (7/1998 to 7/2000). It deteriorates sharply in the following period (8/2000 to 6/2003), and levels out in the later periods (7/2003 to 12/2008).
- The performance of the EBITDA/EV factor is consistently positive in the early periods (12/1989 to 9/1998), deteriorates in the next period (10/1998 to 1/2000) and rebounds sharply (2/2000 to 7/2002), grows at a slower but more historically consistent rate in the later periods (8/2002 to 4/2007), deteriorates in the next period (5/2007 to 9/2007), and returns to more historically consistent returns in last period (10/2007 to 12/2008).
- The cumulative return of the share repurchase factor grows at a slower pace in the early years (12/1989 to 5/1999), falls slightly in the middle periods (6/1999 to 1/2000), rebounds sharply (2/2000 to 7/2002), falls then flattens out in the next period (8/2002 to 4/2008), and increases at a large rate late in the graph (5/2008 to 12/2008).
- The momentum factor experiences the largest volatility. This factor performs consistently well in the early period (12/1989 to 12/1998),

Earnings growth	-0.14	-0.49	0.58	-0.05	1.00

Figure 7 Summary of Monthly Factor Information Coefficients

experiences sharp volatility in the middle period (1/1999 to 5/2003), flattens out (6/2003 to 6/2007), and grows at an accelerating rate from (7/2007 to 12/2008).

- The performance of the earnings growth factor is flat or negative throughout the entire period.

The overall pattern of the cumulative returns among the factors clearly illustrates that factor returns and correlations are time varying.

In Figure 7(A), we present summary statistics of the monthly information coefficients of the factors. The average monthly information coefficients range from 0.03 for EBITDA/EV and momentum, to 0.01 for the share repurchase factor. The *t*-statistics for the mean ICs are significant at the 95% level for all factors except earnings growth. With the exception of share repurchase and earnings growth, the fraction of positive returns of the factors are significantly greater than that of the negative returns.

The share repurchase factor requires some comments. The information coefficient is negative, in contrast to the positive return in the long-short portfolio sorts, because negative share repurchases are correlated with subsequent return. The information coefficient is lower than we would expect because there is

not a strong linear relation between the return and the measures. As the results from the portfolio sorts indicate, the extreme values of this factor provide the highest returns.

Figure 7(B) displays unconditional correlation coefficients of the monthly information coefficients. The comovement of the ICs factor returns varies among the factors. The lowest correlation is -0.66 between EBITDA/EV and share repurchases. But again this should be interpreted with caution because it is negative repurchases that we view as attractive. The highest correlation reported in the exhibit is 0.79 between momentum and revisions. Similar to the correlation of long-short factor portfolio returns, the diverse set of correlations provides evidence that combining uncorrelated factors may produce a successful strategy.

In Figure 8(A), we present summary statistics of the time series average of the monthly coefficients from the Fama-MacBeth (FM) regressions of the factors. The information provided by the FM coefficients differs from the information provided by portfolio sorts. The FM coefficients show the linear relationship between the factor and subsequent returns, while the results from the portfolio sorts provide information on the extreme values of the factors and subsequent returns. The difference in the

Momentum	0.77	-0.18	-0.04	1.00	-0.18
Earnings growth	-0.26	-0.58	0.64	-0.18	1.00

Figure 8 Summary of Monthly Fama-MacBeth Regression Coefficients

size of the mean returns between the FM coefficients and portfolio sorts exits partially because the intercept terms from the FM regressions are not reported in the exhibit.

The average monthly FM coefficient ranges from -0.18 for share repurchase to 0.31 for the momentum factor. Again the share repurchase results should be interpreted with caution because it is negative repurchases that we view as attractive. The *t*-statistics are significant at the 95% level for the EBITDA/EV and share repurchase factors.

Also, we compare the results of portfolio sorts in Figure 7(A) with the FM coefficients in Figure 8(A). The rank ordering of the magnitude of factor returns is similar between the two panels. The *t*-statistics are slightly higher in the FM regressions than the portfolio sorts. The correlation coefficients for the portfolio sorts in Figure 7(B) are consistent with the FM coefficients in Figure 8(B) for all the factors except for shares repurchases. The results for share repurchases need to be interpreted with caution because it is negative repurchases that we view as attractive. The portfolio sorts take that into account while FM regressions do not.

To better understand the time variation of the performance of these factors, we calculate rolling 24-month mean returns and correlations

of the factors. The results are presented in Figure 9. We see that the returns and correlations to all factors are time varying. A few of the time series experience large volatility in the rolling 24-month returns. The EBITDA/EV factor shows the largest variation followed by the momentum and share repurchase factors. All factors experience periods where the rolling average returns are both positive and negative.

Figure 10 presents the rolling correlation between pairs of the factors. There is substantial variability in many of the pairs. In most cases the correlation moves in a wave-like pattern. This pattern highlights the time-varying property of the correlations among the factors. This property will be important to incorporate in a factor trading model. The most consistent correlation is between momentum and revisions factors and this correlation is, in general, fairly high.

MODEL CONSTRUCTION METHODOLOGIES FOR A FACTOR-BASED TRADING STRATEGY

In the previous section, we analyzed the performance of each factor. The next step in

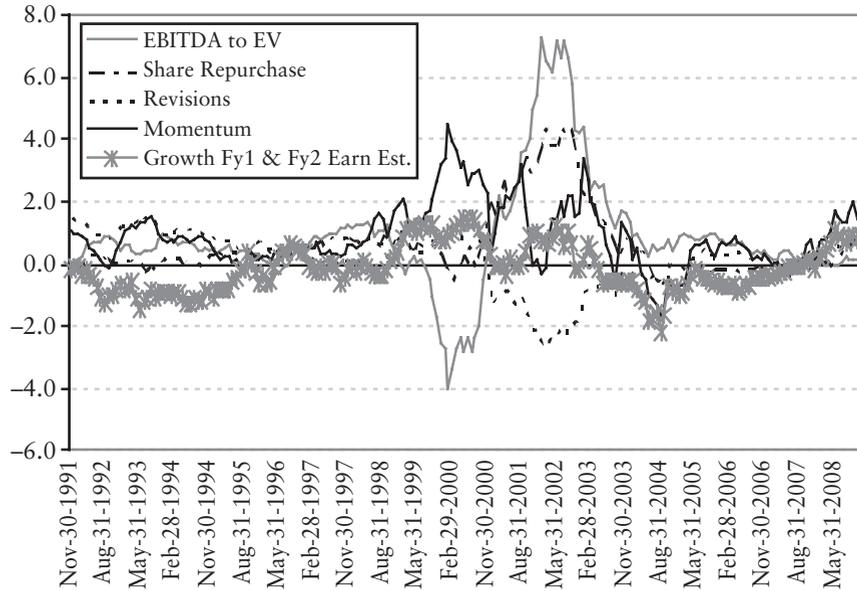

Figure 9 Rolling 24-Month Mean Returns for the Factors

building our trading strategy is to determine how to combine the factors into one model. The key aspect of building this model is to (1) determine what factors to use out of the universe of factors that we have, and (2) how to weight them.

We describe four methodologies to combine and weight factors to build a model for a trading strategy. These methodologies are used to translate the empirical work on factors into a working model. Most of the methodologies are flexible in their specification and there is

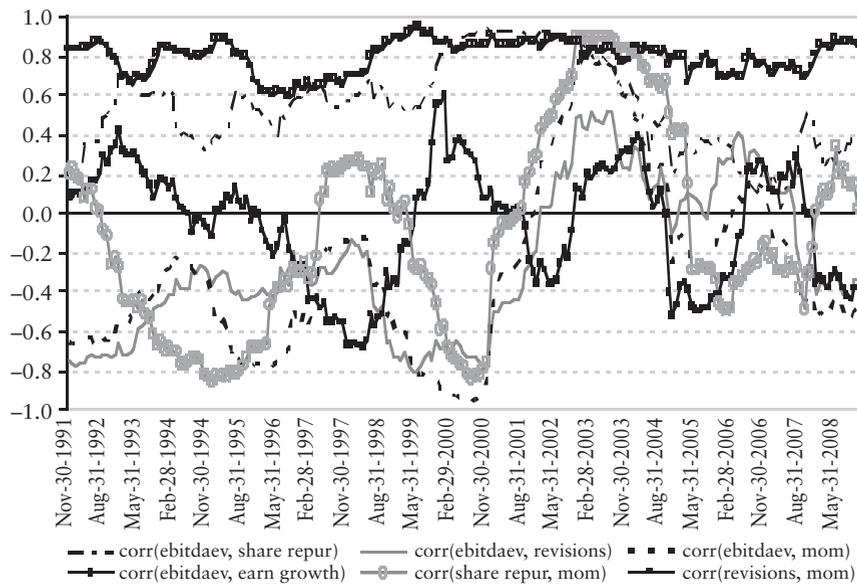

Figure 10 Rolling 24-Month Correlations of Monthly Returns for the Factors

some overlap between them. Though the list is not exhaustive, we highlight those processes frequently used by quantitative portfolio managers and researchers today. The four methodologies are the data driven, the factor model, the heuristic, and the optimization approaches.

It is important to be careful how each methodology is implemented. In particular, it is critical to balance the iterative process of finding a robust model with good forecasting ability versus finding a model that is a result of data mining.

The Data Driven Approach

A *data driven approach* uses statistical methods to select and weight factors in a forecasting model. This approach uses returns as the independent variables and factors as the dependent variables. There are a variety of estimation procedures, such as neural nets, classification trees, and principal components, that can be used to estimate these models. Usually a statistic is established to determine the criteria for a successful model. The algorithm of the statistical method evaluates the data and compares the results against the criteria.

Many data driven approaches have no structural assumptions on potential relationships the statistical method finds. Therefore, it is sometimes difficult to understand or even explain the relationship among the dependent variables used in the model.

Deistler and Hamann (2005) provide an example of a data driven approach to model development. The model they develop is used for forecasting the returns to financial stocks. To start, they split their data sample into two parts—an in-sample part for building the model and an out-of-sample part to validate the model. They use three different types of factor models for forecasting stock returns: quasistatic principal components, quasistatic factor models with idiosyncratic noise, and reduced rank regression. For model selection Deistler

and Hamann use an iterative approach where they find the optimal mix of factors based on the Akaike's information criterion and the Bayesian information criterion. A large number of different models are compared using the out-of-sample data. They find that the reduced rank model provides the best performance. This model produced the highest out-of-sample R^2 s, hit rates,¹⁶ and Diebold-Mariano test statistic¹⁷ among the different models evaluated.

The Factor Model Approach

In this section, we briefly address the use of factor models for forecasting. The goal of the factor model is to develop a parsimonious model that forecasts returns accurately. One approach is for the researcher to predetermine the variables to be used in the factor model based on economic intuition. The model is estimated and then the estimated coefficients are used to produce the forecasts.

A second approach is to use statistical tools for model selection. In this approach we construct several models—often by varying the factors and the number of factors used—and have them compete against each other, just like a horse race. We then choose the best performing model.

Factor model performance can be evaluated in three ways. We can evaluate the fit, forecast ability, and economic significance of the model. The measure to evaluate the fit of a model is based on statistical measures including the model's R^2 and adjusted R^2 , and F - and t -statistics of the model coefficients.

There are several methods to evaluate how well a model will forecast. West (2004) discusses the theory and conventions of several measures of relative model quality. These methods use the resulting time series of predictions and prediction errors from a model. In the case where we want to compare models, West suggests ratios or differences of mean; mean-square or mean-absolute prediction errors; correlation between

one model's prediction and another model's realization (also known as forecast encompassing); or comparison of utility or profit-based measures of predictive ability. In other cases where we want to assess a single model, he suggests measuring the correlation between prediction and realization, the serial correlation in one step ahead prediction errors, the ability to predict direction of change, and the model prediction bias.

We can evaluate economic significance by using the model to predict values and using the predicted values to build portfolios. The profitability of the portfolios is evaluated by examining statistics such as mean returns, information ratios, dollar profits, and drawdown.

The Heuristic Approach

The *heuristic approach* is another technique used to build trading models. Heuristics are based on common sense, intuition, and market insight and are not formal statistical or mathematical techniques designed to meet a given set of requirements. Heuristic-based models result from the judgment of the researcher. The researcher decides the factors to use, creates rules in order to evaluate the factors, and chooses how to combine the factors and implement the model.

Piotroski (2000) applies a heuristic approach in developing an investment strategy for high-value stocks (high book-to-market firms). He selects nine fundamental factors¹⁸ to measure three areas of the firm's financial condition: profitability, financial leverage and liquidity, and operating efficiency. Depending on the factor's implication for future prices and profitability, each factor is classified as either "good" or "bad." An indicator variable for the factor is equal to one (zero) if the factor's realization is good (bad). The sum of the nine binary factors is the F_SCORE. This aggregate score measures the overall quality, or strength, of the firm's financial position. According to the historical re-

sults provided by Piotroski, this trading strategy is very profitable. Specifically, a trading strategy that buys expected winners and shorts expected losers would have generated a 23% annual return between 1976 and 1996.

There are different approaches to evaluate a heuristic approach. Statistical analysis can be used to estimate the probability of incorrect outcomes. Another approach is to evaluate economic significance. For example, Piotroski determines economic significance by forming portfolios based on the firm's aggregate score (F_SCORE) and then evaluates the size of the subsequent portfolio returns.

There is no theory that can provide guidance when making modeling choices in the heuristic approach. Consequently, the researcher has to be careful not to fall into the data-mining trap.

The Optimization Approach

In this approach, we use optimization to select and weight factors in a forecasting model. An *optimization approach* allows us flexibility in calibrating the model and simultaneously optimizing an objective function specifying a desirable investment criteria.

There is substantial overlap between optimization use in forecast modeling and portfolio construction. There is frequently an advantage in working with the factors directly, as opposed to all individual stocks. The factors provide a lower dimensional representation of the complete universe of the stocks considered. Besides the dimensionality reduction, which reduces computational time, the resulting optimization problem is typically more robust to changes in the inputs.

Sorensen, Hua, Qian, and Schoen (2004) present a process that uses an optimization framework to combine a diverse set of factors (alpha sources) into a multifactor model. Their procedure assigns optimal weights across the factors to achieve the highest information ratio. They show that the optimal weights are a

function of average ICs and IC covariances. Specifically,

$$\mathbf{w} \propto \text{cov}(\mathbf{IC})^{-1} \times \overline{\mathbf{IC}}$$

where \mathbf{w} is the vector of factor weights, $\overline{\mathbf{IC}}$ is the vector of the average of the risk-adjusted ICs, and $\text{cov}(\mathbf{IC})^{-1}$ is the inverse of the covariance matrix of the ICs.

In a subsequent paper, Sorensen, Hua, and Qian (2005) apply this optimization technique to capture the idiosyncratic return behavior of different security contexts. The contexts are determined as a function of stock risk characteristics (value, growth, or earnings variability). They build a multifactor model using the historical risk-adjusted IC of the factors, determining the weights of the multifactor model by maximizing the IR of the combined factors. Their research demonstrates that the weights to factors of an alpha model (trading strategy) differ depending on the security contexts (risk dimensions). The approach improves the ex post information ratio compared to a model that uses a one-size-fits-all approach.

Importance of Model Construction and Factor Choice

Empirical research shows that the factors and the weighting scheme of the factors are important in determining the efficacy of a trading strategy model. Using data from the stock selection models of 21 major quantitative funds, the quantitative research group at Sanford Bernstein analyzed the degree of overlap in rankings and factors.¹⁹ They found that the models maintained similar exposures to many of the same factors. Most models showed high exposure to cash flow-based valuations (e.g., EV/EBITDA) and price momentum, and less exposure to capital use, revisions, and normalized valuation factors. Although they found commonality in factor exposures, the stock rankings and performance of the models were substantially different. This surprising finding indicates that model construction differs among

the various stock selection models and provides evidence that the efficacy of common signals has not been completely arbitrated away.

A second study by the same group showed commonality across models among cash flow and price momentum factors, while stock rankings and realized performance were vastly different.²⁰ They hypothesize that the difference between good and poor performing models may be related to a few unique factors identified by portfolio managers, better methodologies for model construction (e.g., static, dynamic, or contextual models), or good old-fashioned luck.

Example: A Factor-Based Trading Strategy

In building this model, we hope to accomplish the following objectives: identify stocks that will outperform and underperform in the future, maintain good diversification with regard to alpha sources, and be robust to changing market conditions such as time varying returns, volatilities, and correlations.

We have identified 10 factors that have an ability to forecast stock returns.²¹ Of the four model construction methodologies discussed previously, we use the optimization framework to build the model as it offers the greatest flexibility.

We determine the allocation to specific factors by solving the following optimization problem:

$$\begin{aligned} \min_w \quad & \mathbf{w}'\Sigma\mathbf{w}, \quad \mathbf{w} \geq 0 \\ & \sum_{v \in \text{Value}} \mathbf{w}_v \geq 0.35 \\ & \sum_{g \in \text{Growth}} \mathbf{w}_g \geq 0.20 \\ & 3 \leq \sum_{i=1}^{10} \delta_i \leq 7 \end{aligned}$$

with the budget constraint

$$\mathbf{w}'\mathbf{e} = 1, \quad \mathbf{e} = (1, \dots, 1)'$$

where Σ is the covariance matrix of factor returns, Value and Growth are the sets of value and growth factors, and δ_i is equal to one if $w_i > 0$ or zero otherwise.

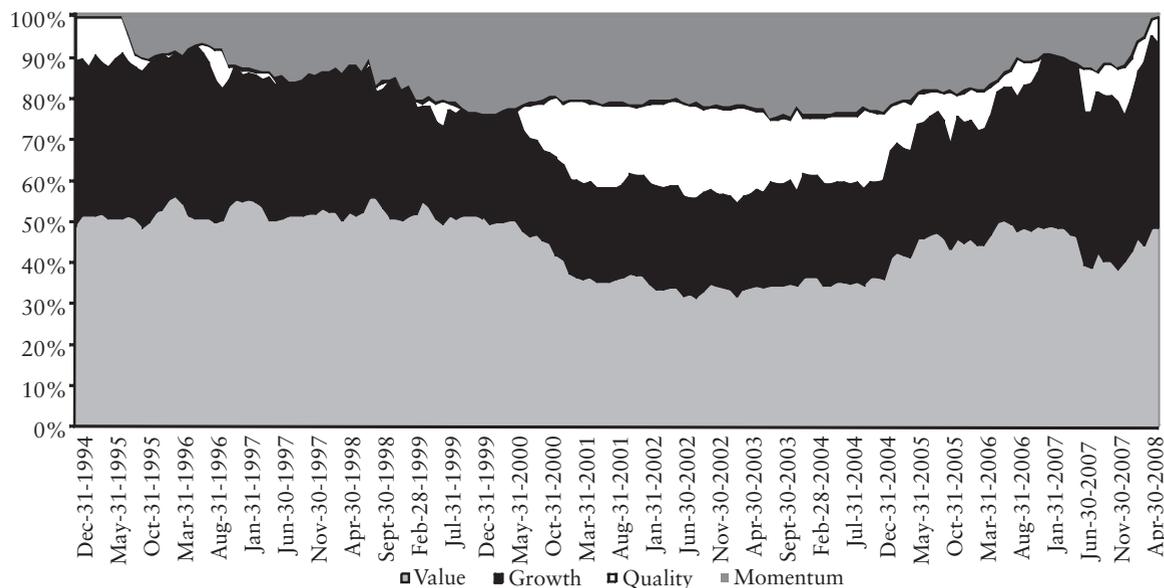

Figure 11 Factor Weights of the Trading Strategy

We constrain the minimum exposure to values factors to be greater than or equal to 35% of the weight in the model based on the belief that there is a systematic long-term premium to value.

Using the returns of our factors, we perform this optimization monthly to determine which factors to hold and in what proportions. Figure 11 displays how the factor weights change over time.

In the next step, we use the factor weights to determine the attractiveness of the stocks in our universe. We score each stock in the universe by multiplying the standardized values of the factors by the weights provided by the optimization of our factors. Stocks with high scores are deemed attractive and stocks with low scores are deemed unattractive.

To evaluate how the model performs, we sort the scores of stocks into five equally weighted portfolios and evaluate the returns of these portfolios. Table 1(A) provides summary statistics of the returns for each portfolio. Note that there is a monotonic increasing relationship among the portfolios with portfolio 1 (q1) earning the highest return and portfolio 5 (q5) earn-

ing the lowest return. Over the entire period, the long-short portfolio (LS) that is long portfolio 1 and short portfolio 5 averages about 1% per month with a monthly Sharpe ratio of 0.33. Its return is statistically significant at the 97.5% level.

Table 1 Summary of Model Results

Min	0.07	0.05
Num	169	169
t-statistic	36.74	39.17

Table 1(B) shows the monthly average stock turnover of portfolio 1 (q1) and portfolio 5 (q5). Understanding how turnover varies from month to month for a trading strategy is important. If turnover is too high then it might be prohibitive to implement because of execution costs. While beyond the scope of this entry, we could explicitly incorporate transaction costs in this trading strategy using a market impact model.²² Due to the dynamic nature of our trading strategy—where active factors may change from month to month—our turnover of 20% is a bit higher than what would be expected using a static approach.

We evaluate the monthly information coefficient between the model scores and subsequent return. This analysis provides information on how well the model forecasts return. The monthly mean information coefficient of the model score is 0.03 and is statistically sig-

nificant at the 99% level. The monthly standard deviation is 0.08. We note that both the information coefficients and returns were stronger and more consistent in the earlier periods.

Figure 12 displays the cumulative return to portfolio 1 through portfolio 5. Throughout the entire period there is a monotonic relationship between the portfolios. To evaluate the overall performance of the model, we analyze the performance of the long-short portfolio returns. We observe that the model performs well in December 1994 to May 2007 and April 2008 to June 2008. This is due to the fact that our model correctly picked the factors that performed well in those periods. We note that the model performs poorly in the period July 2007–April 2008, losing an average of 1.09% a month. The model appears to suffer from the same problems many quantitative equity funds and hedge funds faced during this period.²³

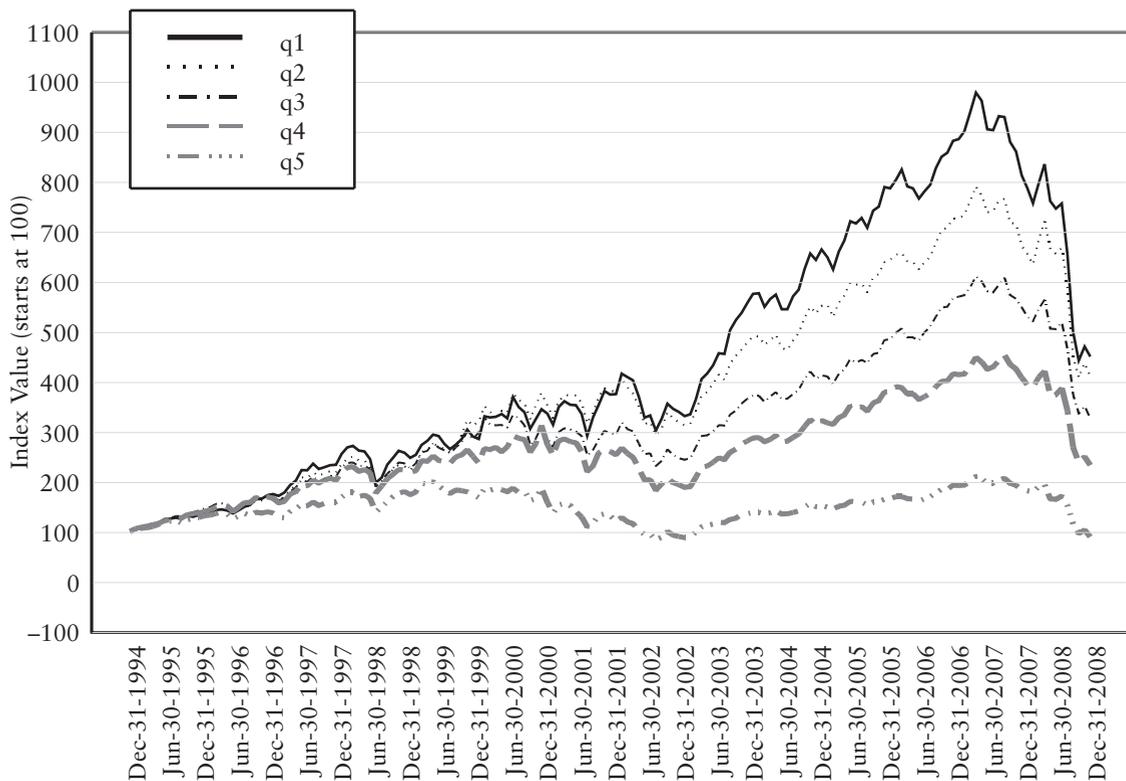

Figure 12 Cumulative Return of the Model

The worst performance in a single month was -6.87 , occurring in January 2001, and the maximum drawdown of the model was -13.7% , occurring during the period from May 2006 (peak) to June 2008 (trough).²⁴

To more completely understand the return and risk characteristic of the strategy, we would have to perform a more detailed analysis, including risk and performance attribution, and model sensitivity analysis over the full period as well as over subperiods. As the turnover is on the higher side, we may also want to introduce turnover constraints or use a market impact model.

Periods of poor performance of a strategy should be disconcerting to any analyst. The poor performance of the model during the period June 2007–March 2008 indicates that many of the factors we use were not working. We need to go back to each individual factor and analyze them in isolation over this time frame. In addition, this highlights the importance of research to improve existing factors and develop new ones using unique data sources.

BACKTESTING

In the research phase of the trading strategy, model scores are converted into portfolios and then examined to assess how these portfolios perform over time. This process is referred to as *backtesting a strategy*. The backtest should mirror as closely as possible the actual investing environment incorporating both the investment's objectives and the trading environment.

When it comes to mimicking the trading environment in backtests, special attention needs to be given to transaction costs and liquidity considerations. The inclusion of transaction costs is important because they may have a major impact on the total return. Realistic market impact and trading costs estimates affect what securities are chosen during portfolio construction. Liquidity is another attribute that needs to be evaluated. The investable universe of

stocks should be limited to stocks where there is enough liquidity to be able to get in and out of positions.

Portfolio managers may use a number of constraints during portfolio construction. Frequently these constraints are derived from the portfolio policy of the firm, risk management policy, or investor objectives. Common constraints include upper and lower bounds for each stock, industry, or risk factor—as well as holding size limits, trading size limits, turnover, and the number of assets long or short.

To ensure the portfolio construction process is robust we use sensitivity analysis to evaluate our results. In sensitivity analysis we vary the different input parameters and study their impact on the output parameters. If small changes in inputs give rise to large changes in outputs, our process may not be robust enough. For example, we may eliminate the five best and worst performing stocks from the model, rerun the optimization, and evaluate the performance. The results should be similar as the success of a trading strategy should not depend on a handful of stocks.

We may want to determine the effect of small changes in one or more parameters used in the optimization. The performance of the optimal portfolio should in general not differ significantly after we have made these small changes.

Another useful test is to evaluate a model by varying the investment objective. For example, we may evaluate a model by building a low-tracking-error portfolio, a high-tracking-error portfolio, and a market-neutral portfolio. If the returns from each of these portfolios are decent, the underlying trading strategy is more likely to be robust.

Understanding In-Sample and Out-of-Sample Methodologies

There are two basic backtesting methodologies: in-sample and out-of-sample. It is important to understand the nuances of each.

We refer to a backtesting methodology as an in-sample methodology when the researcher uses the same data sample to specify, calibrate, and evaluate a model.

An out-of-sample methodology is a backtesting methodology where the researcher uses a subset of the sample to specify and calibrate a model, and then evaluates the forecasting ability of the model on a different subset of data. There are two approaches for implementing an out-of-sample methodology. One approach is the split-sample method. This method splits the data into two subsets of data where one subset is used to build the model while the remaining subset is used to evaluate the model.

A second method is the recursive out-of-sample test. This approach uses a sequence of recursive or rolling windows of past history to forecast a future value and then evaluates that value against the realized value. For example, in a rolling regression-based model we will use data up to time t to calculate the coefficients in the regression model. The regression model forecasts the $t + h$ dependent values, where $h > 0$. The prediction error is the difference between the realized value at $t + h$ and the predicted value from the regression model. At $t + 1$ we recalculate the regression model and evaluate the predicted value of $t + 1 + h$ against realized value. We continue this process throughout the sample.

The conventional thinking among econometricians is that in-sample tests tend to reject the null hypotheses of no predictability more often than out-of-sample tests. This view is supported by many researchers because they reason that in-sample tests are unreliable, often finding spurious predictability. Two reasons given to support this view are the presence of unmodeled structural changes in the data and the use of techniques that result in data mining and model overfitting.

Inoue and Kilian (2002) question this conventional thinking. They use asymptotic theory to evaluate the “trade-offs between in-sample tests and out-of-sample tests of predictability

in terms of their size and power.” They argue strong in-sample results and weak out-of-sample results are not necessarily evidence that in-sample tests are not reliable. Out-of-sample tests using sample-splitting result in a loss of information and lower power for small samples. As a result, an out-of-sample test may fail to detect predictability while the in-sample test will correctly identify predictability. They also show that out-of-sample tests are not more robust to parameter instability that results from unmodeled structural changes.

A Comment on the Interaction between Factor-Based Strategies and Risk Models

Frequently, different factor models are used to calculate the risk inputs and the expected return forecasts in a portfolio optimization. A common concern is the interaction between factors in the models for risk and expected returns. Lee and Stefek (2008) evaluate the consequences of using different factor models, and conclude that (1) using different models for risk and alpha can lead to unintended portfolio exposures that may worsen performance; (2) aligning risk factors with alpha factors may improve information ratios; and (3) modifying the risk model by including some of the alpha factors may mitigate the problem.

BACKTESTING OUR FACTOR TRADING STRATEGY

Using the model scores from the trading strategy example, we build two optimized portfolios and evaluate their performance. Unlike the five equally weighted portfolios built only from model scores, the models we now discuss were built to mirror as close as possible tradable portfolios a portfolio manager would build in real time. Our investable universe is the Russell 1000. We assign alphas for all stock in the Russell 1000 with our dynamic factor model.

Table 2 Total Return Report (annualized)

From 01/1995 to 06/2008	QTD	YTD	1 Year	2 Year	3 Year	5 Year	10 Year	Since Inception
Portfolio: Low-tracking error	-0.86	-10.46	-11.86	4.64	7.73	11.47	6.22	13.30
Portfolio: High-tracking error	-1.43	-10.47	-11.78	4.15	8.29	13.24	7.16	14.35
S&P 500: Total return	-2.73	-11.91	-13.12	2.36	4.41	7.58	2.88	9.79

The portfolios are long only and benchmarked to the S&P 500. The difference between the portfolios is in their benchmark tracking error. For the low-tracking error portfolio the risk aversion in the optimizer is set to a high value, sectors are constrained to plus or minus 10% of the sector weightings in the benchmark, and portfolio beta is constrained to 1.00. For the high-tracking error portfolio, the risk aversion is set to a low value, the sectors are constrained to plus or minus 25% of the sector weightings in the benchmark, and portfolio beta is constrained to 1.00. Rebalancing is performed once a month. Monthly turnover is limited to 10% of the portfolio value for the low-tracking error portfolio and 15% of the portfolio value for the high-tracking error portfolio.

Table 2 presents the results of our backtest. The performance numbers are gross of fees and transaction costs. Performance over the entire period is good and consistent throughout. The portfolios outperform the benchmark over the various time periods. The resulting annualized Sharpe ratios over the full period are 0.66 for the low-tracking error portfolio, 0.72 for the high-tracking error portfolio, and 0.45 for the S&P 500.²⁵

KEY POINTS

- The four most commonly used approaches for the evaluation of return premiums and risk characteristics to factors are portfolio sorts, factor models, factor portfolios, and information coefficients.
- The portfolio sorts approach ranks stocks by a particular factor into a number of portfolios. The sorting methodology should be consis-

tent with the characteristics of the distribution of the factor and the economic motivation underlying its premium.

- The information ratio (IR) is a statistic for summarizing the risk-adjusted performance of an investment strategy and is defined as the ratio of average excess return to the standard deviation of return.
- We distinguish between contemporaneous and forecasting factor models, dependent on whether both left- and right-hand side variables (returns and factors) have the same time subscript, or the time subscript of the left-hand side variable is greater.
- The three most common violations of classical regression theory that occur in *cross-sectional factor models* are (1) the errors in variables problem, (2) common variation in residuals such as heteroskedasticity and serial correlation, and (3) multicollinearity. There are statistical techniques that address the first two. The third issue is best dealt with by removing collinear variables from the regression, or by increasing the sample size.
- The Fama-MacBeth regression addresses the inference problem caused by the correlation of the residuals in cross-sectional regressions.
- The information coefficient (IC) is used to evaluate the return forecast ability of a factor. It measures the cross-sectional correlation between a factor and its subsequent realized return.
- Factor portfolios are used to measure the information content of a factor. The objective is to mimic the return behavior of a factor and minimize the residual risk. We can build factor portfolios using a factor model or an optimization. An optimization is more flexible as it is able to incorporate constraints.

- Analyzing the performance of different factors is an important part of the development of a factor-based trading strategy. This process begins with understanding the time-series properties of each factor in isolation and then studying how they interact with each other.
- Techniques used to combine and weight factors to build a trading strategy model include the data driven, the factor model, the heuristic, and the optimization approaches.
- An out-of-sample methodology is a backtesting methodology where the researcher uses a subset of the sample to specify a model and then evaluates the forecasting ability of the model on a different subset of data. There are two approaches for implementing an out-of-sample methodology: the split-sample approach and the recursive out-of-sample test.
- Caution should be exercised if different factor models are used to calculate the risk inputs and the expected return forecasts in a portfolio optimization.

APPENDIX: THE COMPUSTAT POINT-IN-TIME, IBES CONSENSUS DATABASES AND FACTOR DEFINITIONS

The factors used in this entry were constructed on a monthly basis with data from the Compustat Point-In-Time and IBES Consensus databases. Our sample includes the largest 1,000 stocks by market capitalization over the period December 31, 1989, to December 31, 2008.

The Compustat Point-In-Time database (Capital IQ, Compustat, <http://www.compustat.com>) contains quarterly financial data from the income, balance sheet, and cash flow statements for active and inactive companies. This database provides a consistent view of historical financial data, both reported data and subsequent restatements, the way it appeared at the

end of any month. Using these data allows the researcher to avoid common data issues such as survivorship and look-ahead bias. The data are available from March 1987.

The Institutional Brokers Estimate System (IBES) database (Thomson Reuters, <http://www.thomsonreuters.com>) provides actual earnings from companies and estimates of various financial measures from sell-side analysts. The estimated financial measures include estimates of earnings, revenue and sales, operating profit, analyst recommendations, and other measures. The data are offered on a summary (consensus) level or detailed (analyst-by-analyst) basis. The U.S. data cover reported earnings estimates and results since January 1976.

The factors used in this entry are defined as follows. (LTM refers to the last four reported quarters.)

Value Factors

Operating income before depreciation to enterprise value = EBITDA/EV
where

$$\begin{aligned} \text{EBITDA} = & \text{Sales LTM (Compustat Item 2)} \\ & - \text{Cost of goods Sales LTM} \\ & \quad \text{(Compustat Item 30)} \\ & - \text{SG\&A Exp (Compustat Item 1)} \end{aligned}$$

and

$$\begin{aligned} \text{EV} = & [\text{Long-term debt (Compustat} \\ & \quad \text{Item 51)} \\ & + \text{Common shares outstanding} \\ & \quad \text{(Compustat Item 61)} \\ & \times \text{Price (PRCCM)} - \text{Cash} \\ & \quad \text{(Compustat Item 36)}] \end{aligned}$$

$$\begin{aligned} \text{Book to price} = & \text{Stockholders' equity total} \\ & \quad \text{(Compustat Item 60)} \\ & \div [\text{Common shares outstanding} \\ & \quad \text{(Compustat Item 59)} \\ & \times \text{Price (PRCCM)}] \end{aligned}$$

$$\begin{aligned} \text{Sales to price} &= \text{Sales LTM (Computstat Item 2)} \\ &\div [\text{Common shares outstanding} \\ &\quad \text{(Computstat Item 61)} \\ &\quad \times \text{Price(PRCCM)}] \end{aligned}$$

Quality Factors

$$\begin{aligned} \text{Share repurchase} &= [\text{Common shares} \\ &\quad \text{outstanding (Computstat Item 61)} - \text{Common} \\ &\quad \text{shares outstanding (Computstat Item 61)} \\ &\quad \text{from 12 months ago}] \div \text{Common shares} \\ &\quad \text{outstanding (Computstat Item 61) from} \\ &\quad \text{12 months ago} \end{aligned}$$

$$\begin{aligned} \text{Asset turnover} &= \text{Sales LTM (Computstat Item 2)} / \\ &\quad [(\text{Assets (Computstat Item 44)} \\ &\quad - \text{Assets (Computstat Item 44)} \\ &\quad \text{from 12 months ago}) / 2] \end{aligned}$$

$$\begin{aligned} \text{Return on invested capital} &= \text{Income} / \\ &\quad \text{Invested capital} \end{aligned}$$

where

$$\begin{aligned} \text{Income} &= \text{Income before extra items LTM} \\ &\quad \text{(Computstat Item 8)} \\ &\quad + \text{Interest expense LTM} \\ &\quad \text{(Computstat Item 22)} \\ &\quad + \text{Minority interest expense LTM} \\ &\quad \text{(Computstat Item 3)} \end{aligned}$$

and

$$\begin{aligned} \text{Invested capital} \\ &= \text{Common equity (Computstat Item 59)} \\ &\quad + \text{Long-term debt (Computstat Item 51)} \\ &\quad + \text{Minority interest (Computstat Item 53)} \\ &\quad + \text{Preferred stock (Computstat Item 55)} \\ \text{Debt to equity} &= \text{Total debt} / \text{Stockholders' equity} \end{aligned}$$

where

$$\begin{aligned} \text{Total debt} &= [\text{Debt in current liabilities} \\ &\quad \text{(Computstat Item 45)} + \text{Long-term debt} \\ &\quad - \text{Total (Computstat Item 51)}] \end{aligned}$$

$$\begin{aligned} \text{and} \\ \text{Stockholders' equity} &= \text{Stockholders' equity} \\ &\quad \text{(Computstat Item 60)} \end{aligned}$$

$$\begin{aligned} \text{Chg. debt to equity} &= (\text{Total debt} - \text{Total debt} \\ &\quad \text{from 12 months ago}) \\ &\quad \div [(\text{Stockholders' equity} \\ &\quad + \text{Stockholders' equity} \\ &\quad \text{from 12 months ago}) / 2] \end{aligned}$$

Growth

$$\begin{aligned} \text{Revisions} &= [\text{Number of up revisions} \\ &\quad \text{(IBES item NUMUP)} \\ &\quad - \text{Number of down revisions (IBES} \\ &\quad \quad \text{item NUMDOWN)}] \\ &\quad \div \text{Number of estimates revisions} \\ &\quad \quad \text{(IBES item NUMEST)} \end{aligned}$$

$$\begin{aligned} \text{Growth of fiscal Year 1 and fiscal Year 2} \\ \text{earnings estimates} &= \text{Consensus mean of FY2} \\ &\quad \text{(IBES item MEANFY2)} \div \text{Consensus mean of} \\ &\quad \text{FY 1 (IBES item MEAN FY1)} - 1 \end{aligned}$$

Momentum

$$\begin{aligned} \text{Momentum} &= \text{Total return of last 11 months} \\ &\quad \text{excluding the most returns from} \\ &\quad \text{the most recent month} \end{aligned}$$

Summary Statistics

The following table contains monthly summary statistics of the factors defined previously. Factor values greater than the 97.5 percentile or less than the 2.5 percentile are considered outliers. We set factor values greater than the 97.5 percentile value to the 97.5 percentile value, and factor values less than the 2.5 percentile value to the 2.5 percentile value, respectively.

	Mean	Standard Deviation	Median	25 Percentile	75 Percentile
EBITDA/EV	0.11	0.06	0.11	0.07	0.15
Book to price	0.46	0.30	0.40	0.24	0.62
Sales to price	0.98	0.91	0.69	0.36	1.25
Share repurchase	0.03	0.09	0.00	-0.01	0.03
Asset turnover	1.83	1.89	1.46	0.64	2.56
Return on invested capital	0.13	0.11	0.11	0.07	0.17
Debt to equity	0.97	1.08	0.62	0.22	1.26
Change in debt to equity	0.10	0.31	0.01	-0.04	0.17
Revisions	-0.02	0.33	0.00	-0.17	0.11
Growth of fiscal year 1 and fiscal year 2 earnings estimates	0.37	3.46	0.15	0.09	0.24
Momentum	13.86	36.03	11.00	-7.96	31.25

NOTES

- For a good overview of the most common issues, see Berk (2000) and references therein.
- Grinold and Kahn (1999) discuss the differences between the t -statistic and the information ratio. Both measures are closely related in their calculation. The t -statistic is the ratio of mean return of a strategy to its standard error. Grinold and Kahn state the related calculations should not obscure the distinction between the two ratios. The t -statistic measures the statistical significance of returns while the IR measures the risk-reward trade-off and the value added by an investment strategy.
- See, for example, Fama and French (2004).
- One approach is to use the Bayesian or model averaging techniques. For more details on the Bayesian approach, see, for example, Rachev, Hsu, Bagasheva, and Fabozzi (2008).
- For a discussion of dealing with these econometric problems, see Chapter 2 in Fabozzi, Focardi, and Kolm (2010).
- We cover Fama-MacBeth regression in this section.
- Fama and French (2004).
- See, for example, Grinold and Kahn (1999) and Qian, Hua, and Sorensen (2007).
- A factor normalized z -score is given by the formula $z\text{-score} = (\mathbf{f} - \bar{\mathbf{f}})/\text{std}(\mathbf{f})$ where \mathbf{f} is the factor, $\bar{\mathbf{f}}$ is the mean, and $\text{std}(\mathbf{f})$ is the standard deviation of the factor.
- We are conforming to the notation used in Qian and Hua (2004). To avoid confusion, Qian and Hua use $\text{dis}()$ to describe the cross-sectional standard deviation and $\text{std}()$ to describe the time series standard deviation.
- The earnings estimates come from the IBES database. See the appendix for a more detailed description of the data.
- This derivation of factor portfolios is presented in Grinold and Kahn (1999).
- See Melas, Suryanarayanan, and Cavaglia (2009).
- An exception is the constraint on the number of assets that results in integer constraints.
- For a more detailed discussion on portfolio optimization problems and optimization software see, for example, Fabozzi, Kolm, Pachamanova, and Focardi (2007).
- The hit rate is calculated as

$$h = \frac{1}{T_2 - T_1} \sum_{t=T_1+1}^{T_2} \text{sign}(y_t^i \hat{y}_{t-1}^i)$$
 where y_t^i is *one-step ahead* realized value and \hat{y}_{t-1}^i is the *one-step ahead* predicted value.
- For calculation of this measure, see Diebold and Mariano (2005).
- The nine factors are return on assets, change in return on assets, cash flow from

operations scaled by total assets, cash compared to net income scaled by total assets, change in long-term debt/assets, change in current ratio, change in shares outstanding, change in gross margin, and change in asset turnover.

19. Zlotnikov, Larson, Cheung, Kalaycioglu, Lao, and Apoian (2007).
20. Zlotnikov, Larson, Wally, Kalaycioglu, Lao, and Apoian (2007).
21. We use a combination of growth, value, quality, and momentum factors. The appendix to this entry contains definitions of all of them.
22. Cerniglia and Kolm (2010).
23. See Rothman (2007) and Daniel (2007).
24. We ran additional analysis on the model by extending the holding period of the model from 1 to 3 months. The results were much stronger as returns increased to 1.6% per month for a two-month holding period and 1.9% per month for a three-month holding period. The risk as measured by drawdown was higher at -17.4% for a two-month holding period and -29.5% for the three-month holding period.
25. Here we calculate the Sharpe ratio as portfolio excess return (over the risk-free rate) divided by the standard deviation of the portfolio excess return.

The Fundamentals of Fundamental Factor Models

JENNIFER BENDER, PhD
Vice President, MSCI

FRANK NIELSEN, CFA
Managing Director of Quantitative Research, Fidelity Investments - Global Asset Allocation

Abstract: Fundamental factor risk models have been used in equity portfolio management and risk management for decades now. There persists, however, the notion that fundamental factor models are “quantitative” models that are divorced from fundamental analysis, the realm of traditional equity analysts. This perception is inaccurate in that the basic building blocks of analysts and factor modelers are in fact similar; both try to identify microeconomic traits that drive the risk and returns of individual securities. The differences between fundamental factor models and fundamental analysis lie not in their ideology but in their objectives. The objective of the fundamental analyst is to forecast return (or future stock values) for a particular stock. The objective of the fundamental factor model is to forecast the fluctuation of a portfolio around its expected return. Most importantly, the factor model captures the interaction of the firm’s microeconomic characteristics at the portfolio level. This is important because as names are added to the portfolio, company-specific returns are diversified away, and the common factor (systematic) portion becomes an increasingly larger part of the portfolio risk and return. Fundamental factor models are in fact complementary as opposed to antithetical to traditional security analysis.

Fundamental analysis is the process of determining a security’s future value by analyzing a combination of macro- and microeconomic events and company-specific characteristics. Though fundamental analysis focuses on the valuation of individual companies, most institutional investors recognize that there are common factors affecting all stocks. (Common factors are shared characteristics between firms that affect their

returns.) For example, macroeconomic events, like sudden changes in interest rate, inflation, or exchange rate expectations, can affect all stocks to varying degrees, depending on the stock’s characteristics.

Barr Rosenberg and Vinay Marathe (1976) developed the theory that the effects of macroeconomic events on individual securities could be captured through microeconomic

characteristics—essentially common factors, such as industry membership, financial structure, or growth orientation.

Rosenberg and Marathe (1976, p. 3) discuss possible effects of a money market crisis. They say a money market crisis would:

result in possible bankruptcy for some firms, dislocation of the commercial paper market, and a dearth of new bank lending beyond existing commitments. Firms with high financial risk (shown in extreme leverage, poor coverage of fixed charges, and inadequate liquid assets) might be driven to bankruptcy. Almost all firms would suffer to some degree from higher borrowing costs and worsened economic expectations: Firms with high financial risk would be impacted most; the market portfolio, which is a weighted average of all firms, would be somewhat less exposed; and firms with abnormally low financial risk would suffer the least. Moreover, some industries such as construction would suffer greatly because of their special exposure to interest rates. Others such as liquor might be unaffected.

This early insight into the linkage between macroeconomic events and microeconomic characteristics has had a profound impact on the asset management industry ever since. In this entry, we discuss the intuition behind a fundamental factor model based on microeconomic traits, showing how it is linked to traditional fundamental analysis. When building a fundamental factor model, we look for variables that explain return, just as fundamental analysts do. We highlight the complementary role of the fundamental factor model to traditional security analysis and point out the insights these models can provide.

FUNDAMENTAL ANALYSIS AND THE BARRA FUNDAMENTAL FACTOR MODEL

Fundamental analysts use many criteria when researching companies; they may investigate a firm's financial statements, talk to senior management, visit facilities and plants, or analyze a product pipeline. Most are seeking under-

Table 1 Main Areas of Stock Research

Qualitative	Quantitative
Business Model	Capital Structure
Competitive Advantage	Revenue, Expenses, and Earnings Growth
Management Quality	Cash Flows
Corporate Governance	

Note: Balance sheet and income statement data are readily available from 10K filings while access to company management and information about the business model and competitor landscape will vary on a case-by-case basis.

valued companies with good fundamentals or companies with strong growth potential. They typically review a range of quantitative and qualitative information to help predict future stock values. Table 1 summarizes key areas.

Similarly, the goal of a fundamental factor model is to identify traits that are important in forecasting security risk. These models may analyze microeconomic characteristics, such as industry membership, earnings growth, cash flow, debt-to-assets, and company specific traits. Figure 1 shows the cumulative returns to Merck, GlaxoSmithKline, and Bristol-Myers, three of the largest pharmaceutical companies in the United States. The chart illustrates the similarities in the return behavior of these stocks, primarily because they are U.S. large-cap equities within the same industry. We also see that Bristol-Myers underperformed the other two companies in recent years, indicating that other firm-specific factors also impacted its performance.

The first task when building a fundamental factor model is to identify microeconomic traits. These include characteristics from industry membership and financial ratios to technical indicators like price momentum and recent volatility that explain return variation across a relevant security universe. The next step is to determine the impact certain events may have on individual stocks, such as the sensitivity or weight of an individual security to a change in a given fundamental factor.¹ Finally, the remaining part of the returns needs to be

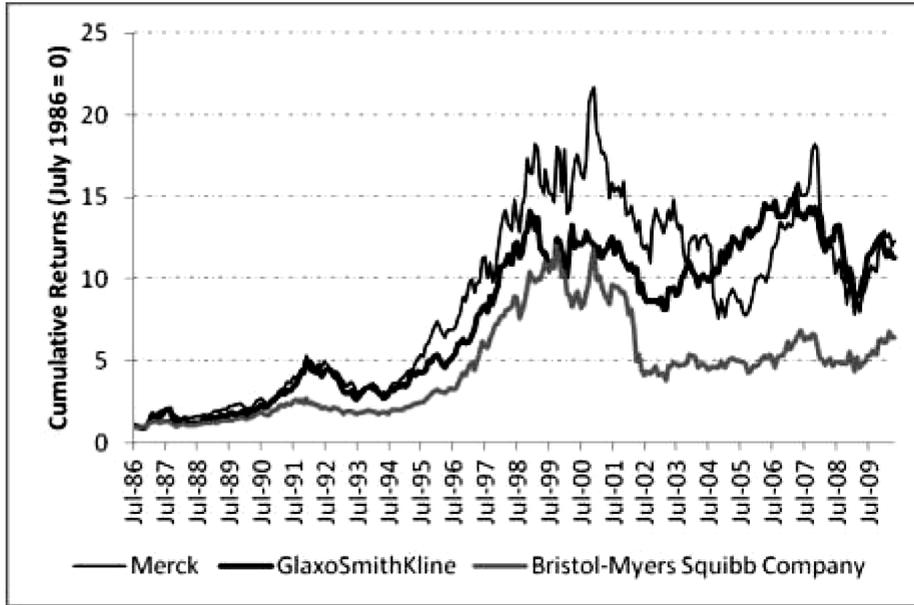

Figure 1 Industry Membership Drives Similarities between Stocks

modeled, which is the company-specific behavior of stocks.

How does the model we have described compare with the way a fundamental analyst or portfolio manager analyzes stocks? The basic building blocks of analysts and factor modelers are in fact similar; both try to identify microeconomic traits that drive the risk and returns of individual securities. Figure 2 compares the two perspectives. In both views, there are clearly firm-specific traits driving risk and return. There are also sources of risk and return from a stock’s exposure, or beta, to the overall market, its industry, and certain financial and technical ratios. But the objective of the fundamental analyst is to forecast return (or future stock values), whereas the fundamental factor model forecasts the fluctuation of a security or a portfolio of securities around its expected return.

Both the analyst and the factor model researcher look at similar macro- and microeconomic data and events. After all, both are seeking traits that explain the risk and returns of stocks. Table 2 shows examples used

in the Barra equity models (specifically the U.S. and Japan Equity Models). Variables like profitability and debt loads are incorporated in our models through factors like Earnings Yield, Growth, and Leverage. Expectations of

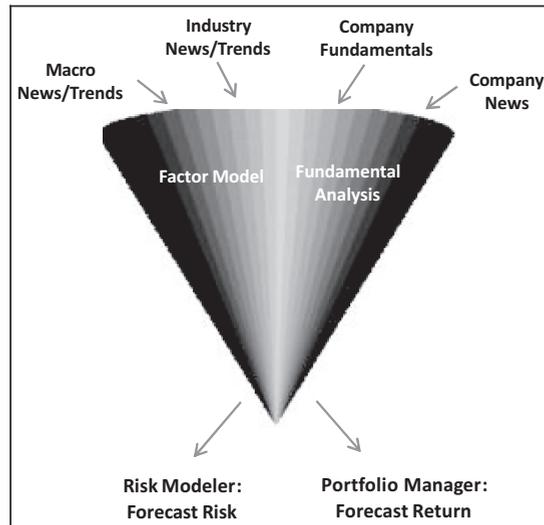

Figure 2 Overview of Stock Determinants: Fundamental Analysis versus Factor Model Analysis

Table 2 Sample Fundamental Data Used in Barra Models

Value	Growth	Earnings Variation	Leverage	Foreign Sensitivity
Book value	Five-year payout	Variability in earnings	Market leverage	Exchange rate sensitivity
Analyst predicted earnings	Variability in capital structure	Standard deviation of analyst-predicted earnings	Book leverage	Oil price sensitivity
Trailing earnings	Growth in total assets	Variability in cash flows	Debt to assets	Sensitivity to other market indices
Forecast operating income	Growth in revenues	Extraordinary items in earnings	Senior debt rating	Export revenue as percentage of total
Sales	Pension liabilities			
Forecast sales	Historical earnings growth			
	Analyst-predicted earnings growth			
	Recent earnings changes			

future revenue growth and cost savings are incorporated through variables like analyst consensus views. What about popular metrics that aren't included? Some factors may not be good risk factors despite being good return factors. (A good return factor has persistent direction though not a lot of volatility; the ability of a company to beat earnings estimates is one of these factors). Other factors may be relevant only for a particular sector or industry. (These risk factors would only be included in industry or sector risk models.)

Note that adjustments of financial statements are incorporated in several ways. A key task for the fundamental analyst is to adjust financial statements—each analyst wants to get at the “real” number rather than what is reported in financial statements. Even under generally accepted accounting principles, management can be aggressive with basic principles, such as revenue/expense recognition; usage of unusual, infrequent, or extraordinary items; and timing issues that may lead to violations of the matching principle. In a factor model, these types of adjustments are accounted for through the inclusion of forward-looking, analyst-derived descriptors.

In addition to fundamental data, technical variables such as price momentum, beta, option-implied volatility, and so on may also be used. For instance, price momentum has been shown to significantly explain returns (see Carhart, 1997).

How are the fundamental data used in a factor model? Certain factors are found to explain stock returns over time, for example, industries and certain financial and technical ratios. If such factors explain returns across a broad universe of stocks, they are deemed important. In financial theory, these factors are “priced” across assets, for example, Fama-French value (BTM) size (small-cap) factors (Fama and French, 1992).

Once we have identified the factors, we need to link each stock to each factor. For this, we use microeconomic characteristics. We start by identifying a set of characteristics we call descriptors. For instance, if the factor is growth, a few descriptors might include earnings growth, revenue growth, and asset growth (see Table 2). These include both historical and forward-looking descriptors, such as forecast earnings growth. After we identify the important descriptors, we standardize them

Table 3 Calculating Exposures from Raw Data (April 1, 2010)

Barra Factor	Size	Value	Yield
Descriptor for Factor	Capitalization (USD Bn)*	Book to Price	Predicted Dividend Yield
Microsoft	256.7	0.15	0.02
Estimation Universe Average	69.8	0.39	0.02
Estimation Universe Std Dev	21.1	0.37	0.02
Exposure	1.64	-0.62	0.06

Note: The actual descriptor for the USE3 Size factor uses the log of market capitalization. The log of market cap for Microsoft is 12.46. The estimation universe average is 10.22 and the standard deviation 1.36. The resulting exposure for Microsoft is 1.64.

across a universe of stocks, typically the constituents of a broad market index.² Table 3 illustrates how Microsoft's exposures for the Barra U.S. factors—size, value, and yield—are calculated. We subtract the estimation universe average³ descriptor for each factor and divide it by the standard deviation of the universe of stocks.

In some cases, factors reflect several characteristics. This occurs when multiple descriptors help explain the same factor. The Barra U.S. Growth factor, for instance, reflects five-year payouts, variability in capital structure, growth in total assets, recent large earnings changes, and forecast and historical earnings growth. Table 4 shows how we calculate Microsoft's exposure to the Growth factor. Each descriptor is first standardized and then the descriptors are combined to form the exposure.

In addition to factors like Value, Size, Yield, and Growth, which we call *style* factors, a stock's returns are also a function of its industry. Industry exposures are calculated in a different way. A company like Google, for instance, is engaged solely in Internet-related activities. It has an exposure of 100% (1.0) to the Internet industry factor in the Barra U.S. Equity Model. Its exposure to all other industry factors is zero. Some companies, like General Electric, have business activities that span multiple industries. In the U.S. model, industry exposures are based on sales, assets, and operating income in each industry.⁴

What does a factor exposure mean? In the same way the classic capital asset pricing model beta measures how much a stock price moves with every percentage change in the market, a factor exposure measures how much a stock

Table 4 Calculating Exposures When There Are Multiple Characteristics (April 1, 2010)

Factor Descriptor	Growth					
	Growth Rate of Total Assets	Recent Earnings Change	Analyst-Predicted Earnings Growth	Variability in Capital Structure	Earnings Growth Rate Over Last 5 Years	5-Year Payout
Microsoft	-0.01%	-0.14	-0.31	25%	0%	0.69
Estimation Universe Average	0.03%	-2.76	1.44	15%	-1%	0.39
Estimation Universe Std Dev	0.04%	47.08	4.36	39%	18%	3.28
Standardized descriptor	-0.95	0.06	-0.40	0.24	0.03	0.09
Weight of each descriptor	-0.34	0.20	0.15	0.13	0.10	0.08
Exposure						-0.33

price moves with every percentage change in a factor. Thus, if the value factor rises by 10%, a stock or portfolio with an exposure of 0.5 to the value factor will see a return of 5%, all else equal.⁵

Once we have predetermined the *factor exposures* for all stocks based on their underlying characteristics, we estimate the factor returns using a regression-based method.⁶

A stock's return can then be described by the returns of its subcomponents: its Size exposure times the return of the Size factor plus its Value exposure times the pure return of the Value factor, and so on. This process can account for a substantial proportion of a stock's return. The remainder of the stock's return is deemed company specific and unique to each security. For example, the return to Microsoft over the last month can be viewed as:

$$r_{MSFT} = x_{Industry_1}r_{Industry_1} + x_{Industry_2}r_{Industry_2} + \dots + x_{Size}r_{Size} + x_{Value}r_{Value} + \dots r_{Firm-Specific}$$

where x is the exposure of Microsoft to the various factors and r_{Factor} denotes returns to the factors.

The returns to the factors are important. They are returns to the particular style or characteristic net of all other factors. For instance, the Value factor is the return to stocks with low price to book ratio with all the industry effects and other style effects removed. Industry returns have a similar interpretation and differ from a Global Industry Classification Standard (GICS®) industry-based return. They are estimated returns that reflect the returns to that industry net of all other style characteristics. They offer insight into the pure returns to the industry.

The final building block of our fundamental factor model is the modeling of company-specific returns. Predicting specific returns and risk is a difficult task that has been approached in a number of ways. The simplest approach is to assume that specific returns and/or risk will be the same as they have been historically. Another approach is to use a structural model

where the predicted specific risk of a company depends on its industry, size, and other fundamental characteristics. Both approaches—simple historical and modeled—are used in the Barra models, depending on the market. The modeled approach has the advantage of using fundamental data.

CRITICAL INSIGHTS FROM THE BARRA FUNDAMENTAL FACTOR MODEL

Fundamental analysis and fundamental *factor models* may begin with the same ideology but they offer different insights. Fundamental analysis ultimately focuses on in-depth company research, while factor models tie the information together at the portfolio level. The critical value of the factor model is that it shows the interaction of the firm's microeconomic characteristics. The value of the factor model at the company level is magnified at the portfolio level as the company-specific component becomes less important. Figure 3 illustrates this principle of diversification. As names are added to the portfolio, company-specific returns are diversified away. Because the common factor (systematic) portion stays roughly the same, it becomes an increasingly larger part of the portfolio risk and return.

This means that at the portfolio level common factors are more important than company-specific drivers in determining a portfolio's return and risk. Understanding and managing the common factor component becomes critical to the portfolio's performance.

The complementary character of fundamental factor models and individual security analysis allows managers to use factor models to analyze portfolio characteristics. Next, we discuss the benefits of using fundamental factor models, including:

- Monitoring and managing portfolio exposures over time

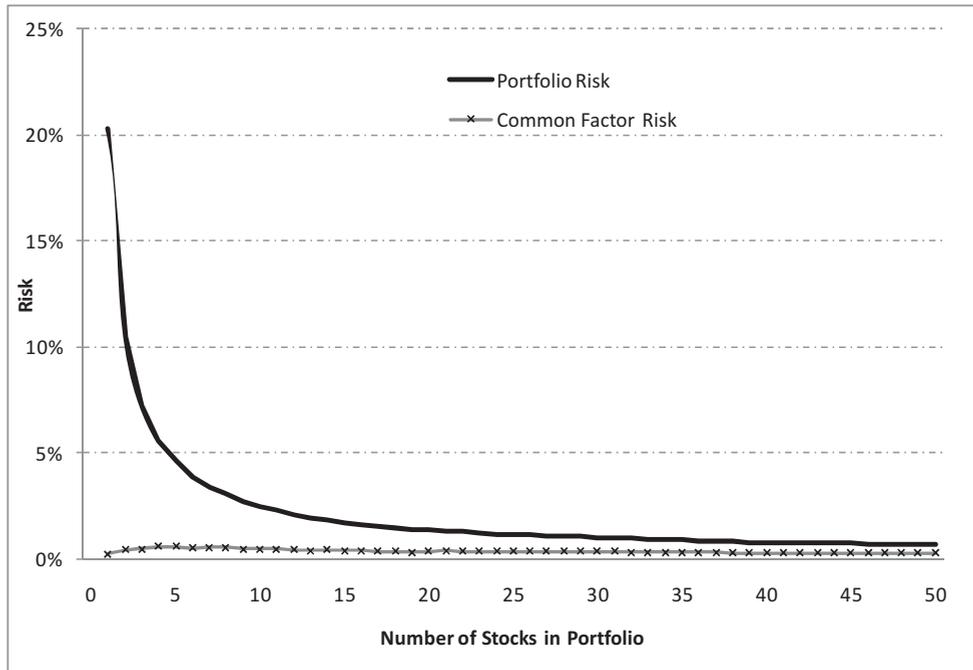

Figure 3 The Number of Stocks and the Impact on the Risk Composition

Note: This chart shows a stylized example of adding stocks to the portfolio where all the stocks have the same specific risk of 20%, there are two factors with risk of 10% and 5%, and correlation between them is 0.25. Factor exposures are drawn from a random distribution. Stocks are weighted equally in the portfolio.

- Understanding the contribution of factors and individual stocks to portfolio risk and tracking error relative to the relevant benchmark (risk decomposition)
- Attributing portfolio performance to factors and individual stocks to understand the return contribution of intended and accidental bets

Monitoring Portfolio Exposures

To illustrate, we use a portfolio of U.S. airline stocks. The concepts can be applied to any sector, multisector, or multicountry portfolio.

Since the middle of 2009, airline stocks have performed well. UAL (United), Delta, and Southwest saw big gains in December 2009 and February 2010. Table 5 lists the largest U.S. airline stocks as of April 30, 2010, with at least USD

1 billion market capitalization and their recent performance.

For the remainder of this section, we look at an equal-weighted portfolio of the stocks in Table 5. Figure 4 shows how the exposures of the airline portfolio to Barra factors evolved over time. The figure shows the top three exposures that changed the most in absolute terms between January 1995 and May 2010. The portfolio had an exposure to the Value factor of 1.8 in January 1995, and by May 2010 the exposure had declined to -0.9 . Essentially, the portfolio went from being relatively cheap to relatively expensive during this time. Airlines have also seen a long-term decrease in exposure to currency sensitivity, most likely due to changes in oil exposure management and global air traffic patterns.

There can also be important differences in the distribution of the stocks' exposures to a

Table 5 Largest Stocks in U.S. Airline Industry and Recent Performance

Company	Ticker	Market Cap (USD Bn)	1 year (3/31/09–3/31/10)	2009 Return	2008 Return
DELTA AIR LINES INC DE	DAL	10.4	111%	–1%	–23%
SOUTHWEST AIRLS CO	LUV	10.2	101%	33%	–29%
UAL CORP	UAUA	3.6	367%	17%	–67%
CONTINENTAL AIRLS [B]	CAL	3.1	109%	–1%	–19%
AMR CORP	AMR	2.8	63%	–28%	–24%
JETBLUE AIRWAYS CORP	JBLU	1.7	32%	–23%	20%
ALASKA AIR GROUP INC	ALK	1.5	161%	18%	17%
ALLEGiant TRAVEL CO	ALGT	1.1	3%	97%	68%
U S AIRWAYS GROUP INC	LCC	1.1	75%	–37%	–47%

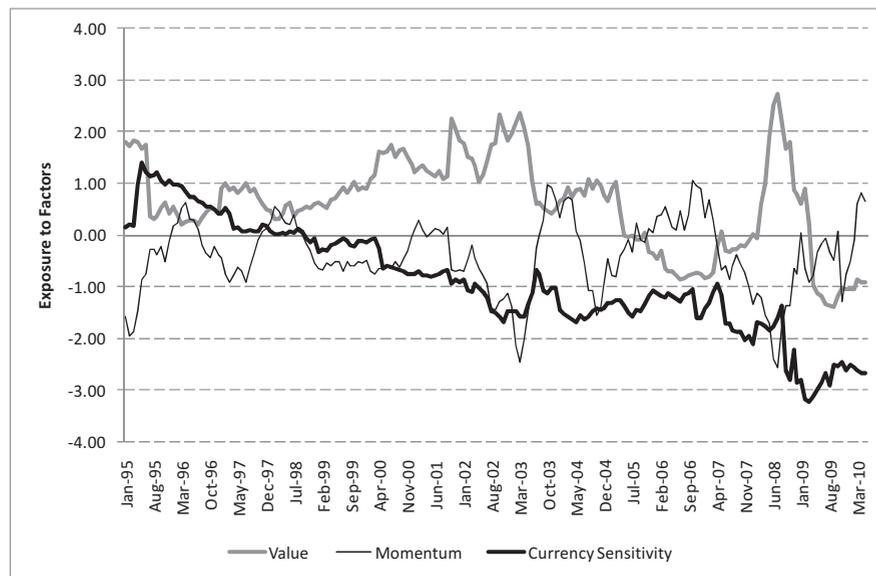

factor. Figure 5 shows the distribution of individual stock exposures to two of the U.S. factors—Value, which has the largest distribution, and Growth, which has among the most narrow distributions—as of May 2010. Two portfolios can have the same overall exposure to a factor but very different distributions.

Monitoring unintentional risk exposures that may not be visible on the surface can be critical. At the portfolio level, these exposures can be unintended bets that can impact overall performance. In addition, the distribution of exposures may be important. For example, a

portfolio of companies with a leverage exposure of zero has a very different economic profile than a portfolio with a barbell distribution where half the companies are overleveraged and potentially vulnerable to a collapse in credit conditions.

RISK DECOMPOSITION

Factor exposures highlight how sensitive a portfolio is to different sources of risk. However, to truly understand how risky these exposures are, we can use the factor model to attribute risk

**Figure 4** Airline Portfolio Exposures over Time

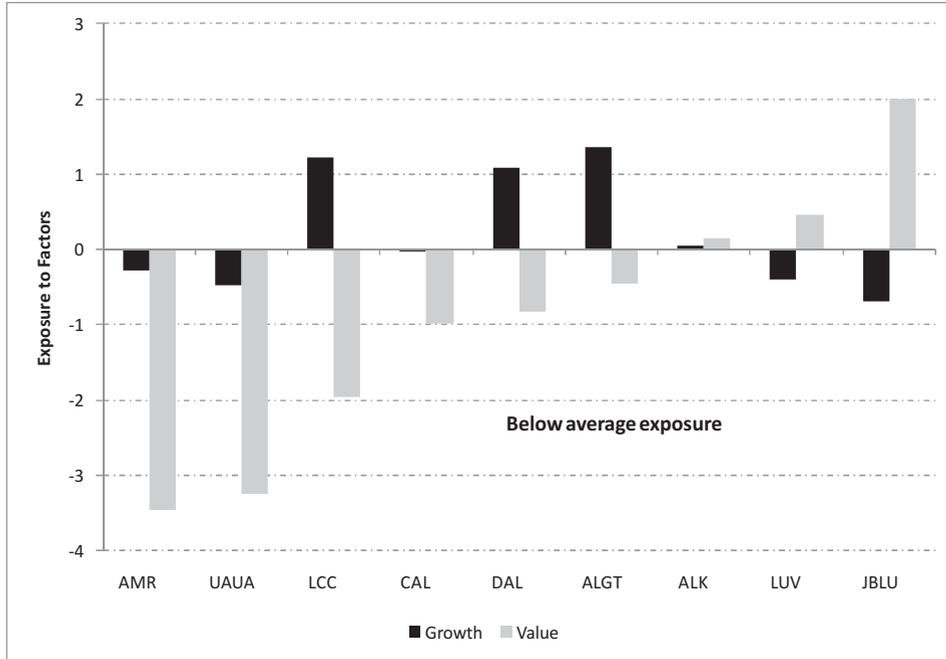

Figure 5 Monitoring the Distribution of Exposures (May 3, 2010)

fully. The combination of exposures and factor volatilities determines the riskiness of each position. For example, a portfolio can have a large exposure to a factor but if the factor isn't particularly risky, it won't be a major contributor to portfolio risk. Furthermore, the relationship between factors also matters. A large exposure to two factors that are highly correlated will also increase portfolio risk.

Continuing with the airline portfolio, we decompose risk as of April 30, 2010 across the four major sources (see Figure 6A). Since the stocks are within a single industry, industry risk contributes the most risk. Most importantly, we see that even with just 9 names in the portfolio, style risk far outweighs company-specific risk. The former contributes nearly three times that of the latter (16% versus 5.5%).

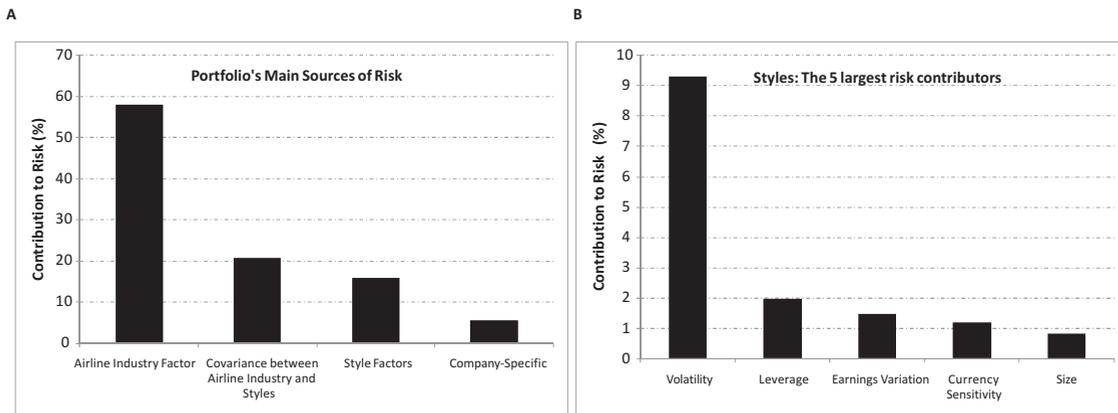

Figure 6 Sources of Risk in an Airline Portfolio, April 30, 2010, Using the Barra U.S. Equity Long-Term Model (USE3L)

Table 6 Exposure to Volatility of Stocks in an Airline Portfolio, April 30, 2010, Using the Barra U.S. Long-Term Equity Model (USE3L)

Portfolio	1.82		
USAir	3.28	JetBlue	1.52
UAL Corp	3.19	Alaska	1.01
AMR	2.70	Southwest	0.49
Continental	1.95	Allegiant	0.39
Delta	1.81		

Which specific style factors drive the style risk? As seen in Figure 6B, the Volatility factor is the biggest contributor by far to risk. This risk stems mostly from USAir and United's high exposure to the factor (see Table 6).

To summarize, *risk decomposition* provides two critical insights. First, as we move from the stock level to the portfolio level, style and industry risk become more important, overtaking company-specific risk. Second, we see that certain styles contribute more risk than others at the stock and portfolio levels. For example, the risk of United (UAL Corp) and USAir will be heavily impacted by the Volatility factor.

Performance Attribution

The fundamental factor model also provides insight into *performance attribution*. Managers can use the model to analyze past performance, attributing realized portfolio return to its various sources. This can include allocations to certain countries or sectors, or allocations to certain segments—small-cap names, emerging markets, or high beta names.

Table 7 shows the decomposition of realized returns for the airline portfolio for April 2010. The first column displays the portfolio return

attribution. The subsequent columns show the return attribution for each individual airline stock in isolation. The portfolio of airline stocks returned -4.3% for the month despite a positive contribution of 4.3% coming from style factors. JetBlue, for instance, was flat for the month, as its gain from style factors largely offset losses from the industry component. Similarly, Continental and UAL were helped by both strong contributions from style exposures. In contrast, positive gains from style factors were not enough to offset the company-specific losses suffered by USAir, Delta, AMR, and Allegiant. In fact, only about half the stocks realized positive company-specific returns.

Table 8 takes the last row in Table 7 and breaks it down into the individual styles in the model. The main source of positive return was the Size factor followed by the Currency Sensitivity, Leverage, and Volatility factors. In other words, airlines benefited from being smaller in cap size relative to the market (exposure of -1.7 to Size). They also benefited from the appreciation of the U.S. dollar (exposure of -2.7 to Currency Sensitivity). In addition, they were helped by being relatively levered (exposure of 2.6 to Leverage) and from having relatively higher overall and higher beta to the market (exposure of 1.7 to Volatility)

At the stock level, most of the airlines benefited from being relatively small. UAL and USAir benefited the most from the appreciation of the U.S. dollar. UAL, USAir, and AMR benefited the most from being relatively more levered than the other airlines. These three stocks also benefited the most from having relatively higher beta to the market and higher volatility.

Table 7 Return Attribution for Airline Portfolio and Stocks, %, March 31, 2010–April 30, 2010, Barra U.S. Equity Long-Term Model (USE3L)

	Portfolio	Alaska	Allegiant	AMR	Continental	Delta	JetBlue	South west	UAL	USAir
Total	-4.3	0.4	-11.1	-19.0	1.7	-17.2	0.2	-0.3	10.4	-3.8

Styles can contribute significantly to a manager's performance. In our example, the U.S. Volatility factor was the main driver. Looking at individual factors and stocks, we can also see that certain factors and stocks made a significant contribution to performance due to stock-specific performance or style contribution.

In summary, portfolio performance can be strongly impacted by unintended bets. The manager may be taking major risks without adequate compensation. The factor model helps uncover these issues.

KEY POINTS

- Fundamental analysis is the process of determining a security's future value by analyzing a combination of macro- and microeconomic events and company-specific characteristics.
- Though fundamental analysis focuses on the valuation of individual companies, most institutional investors recognize that there are common factors affecting all stocks. Common factors are shared characteristics between firms that affect their returns.
- Fundamental factor models are in fact complementary as opposed to antithetical to traditional security analysis. The basic building blocks of analysts and factor modelers are in fact similar: Both try to identify microeconomic traits that drive the risk and returns of individual securities.
- The objective of the fundamental analyst is to forecast return (or future stock values), whereas the fundamental factor model forecasts the fluctuation of a security or a portfolio of securities around its expected return. Some factors may help managers forecast return but not be good risk factors. A good return factor has persistent direction though not a lot of volatility—the ability of a company to beat earnings estimates is one of these factors. A good risk factor may be persistent or not but must be adequately volatile.
- Fundamental analysis and fundamental factor models may begin with the same ideology but they offer different insights. The most critical difference is that the factor model captures the interaction of the firm's microeconomic characteristics at the portfolio level. This is important because as names are added to the portfolio, company-specific returns are diversified away, and the common factor (systematic) portion becomes an increasingly larger part of the portfolio risk and return.
- There are three major benefits of using fundamental factor models: (1) monitoring and managing portfolio exposures over time; (2) understanding the contribution of factors and individual stocks to portfolio risk and tracking error relative to the relevant benchmark (risk decomposition); and (3) attributing portfolio performance to factors and individual

stocks to understand the return contribution of intended and accidental bets.

- Managers can use the model to analyze past performance, attributing realized portfolio return to its various sources. Portfolio performance can be strongly impacted by unintended bets. The manager may be taking major risks without adequate compensation. The factor model helps uncover these issues.
- The distribution of exposures may be important. For example, a portfolio of companies with a leverage exposure of zero has a very different economic profile than a portfolio with a barbell distribution where half the companies are overleveraged and potentially vulnerable to a collapse in credit conditions.

NOTES

1. In the Barra U.S. equity model, for example, we allow companies to be split up into five different industries, depending on their business structure.
2. All existing Barra models focus on a particular market, using an equity universe that includes all sectors and large to mid-caps with some small-caps.
3. The estimation universe average is a market-cap weighted average.
4. In effect, we build three separate valuation models. The results of each valuation model determine a set of weights, based on fundamental information. The final industry weights are a weighted average of the three weighting schemes. Further details are available in the *Barra U.S. Equity Model Handbook*.
5. Specifically, the effects of other factors as well as specific returns remain the same, and the risk-free rate is unchanged.
6. Details of the model construction are available in *The Barra Risk Model Handbook* or *Barra U.S. Equity Model Handbook*.

Abstract: Multifactor equity risk models are classified as statistical models, macroeconomic models, and fundamental models. The most popular types of models used in practice are fundamental models. Many of the inputs used in a multifactor risk model are those used in traditional fundamental analysis. There are several commercially available fundamental multifactor risk models. There are asset management companies that develop proprietary models. Brokerage firms have developed models that they make available to institutional clients.

Quantitative-oriented common stock portfolio managers typically employ a *multifactor equity risk model* in constructing and rebalancing a portfolio and then for evaluating performance. The most popular type of multifactor equity risk model used is a fundamental factor model.¹ While some asset management firms develop their own model, most use commercially available models. In this entry we use one commer-

cially available model to illustrate the general features of *fundamental models* and how they are used to construct portfolios. In our illustration, we will use an old version of a model developed by Barra (now MSCI Barra). Although that model has been updated, the discussion and illustrations provide the essential points for appreciating the value of using multifactor equity models.

MODEL DESCRIPTION AND ESTIMATION

The basic relationship to be estimated in a multifactor risk model is

$$R_i - R_f = \beta_{i,F1} R_{F1} + \beta_{i,F2} R_{F2} + \dots + \beta_{i,FH} R_{FH} + e_i$$

where

R_i = rate of return on stock i

R_f = risk-free rate of return

$\beta_{i,Fj}$ = sensitivity of stock i to risk factor j

R_{Fj} = rate of return on risk factor j

e_i = nonfactor (specific) return on security i

The above function is referred to as a *return generating function*.

Fundamental factor models use company and industry attributes and market data as *descriptors*. Examples are price/earnings ratios, book/price ratios, estimated earnings growth, and trading activity. The estimation of a fundamental factor model begins with an analysis of historical stock returns and descriptors about a company. In the Barra model, for example, the process of identifying the *risk factors* begins with monthly returns for 1,900 companies that the descriptors must explain. Descriptors are not the “risk factors” but instead they are the candidates for risk factors. The descriptors are selected in terms of their ability to explain stock returns. That is, all of the descriptors are potential risk factors but only those that appear to be important in explaining stock returns are used in constructing risk factors.

Once the descriptors that are statistically significant in explaining stock returns are identified, they are grouped into *risk indexes* to capture related company attributes. For example, descriptors such as market leverage, book leverage, debt-to-equity ratio, and company’s debt rating are combined to obtain a risk index referred to as “leverage.” Thus, a risk index is a combination of descriptors that captures a particular attribute of a company.

The Barra fundamental multifactor risk model, the “E3 model” being the latest version, has 13 risk indexes and 55 industry groups. (The descriptors are the same variables that have been consistently found to be important in many well-known academic studies on risk factors.) Table 1 lists the 13 risk indexes in the Barra model.² Also shown in the table are the descriptors used to construct each risk index. The 55 industry classifications are grouped into 13 sectors. For example, the following three industries comprise the energy sector: energy reserves and production, oil refining, and oil services. The consumer noncyclicals sector consists of the following five industries: food and beverages, alcohol, tobacco, home products, and grocery stores. The 13 sectors in the Barra model are basic materials, energy, consumer noncyclicals, consumer cyclicals, consumer services, industrials, utility, transport, health care, technology, telecommunications, commercial services, and financial.

Given the risk factors, information about the exposure of every stock to each risk factor ($\beta_{i,Fj}$) is estimated using statistical analysis. For a given time period, the rate of return for each risk factor (R_{Fj}) also can be estimated using statistical analysis. The prediction for the expected return can be obtained from equation (1) for any stock. The nonfactor return (e_i) is found by subtracting the actual return for the period for a stock from the return as predicted by the risk factors.

Moving from individual stocks to portfolios, the predicted return for a portfolio can be computed. The exposure to a given risk factor of a portfolio is simply the weighted average of the exposure of each stock in the portfolio to that risk factor. For example, suppose a portfolio has 42 stocks. Suppose further that stocks 1 through 40 are equally weighted in the portfolio at 2.2%, stock 41 is 5% of the portfolio, and stock 42 is 7% of the portfolio. Then the exposure of the portfolio to risk factor j is

$$0.022 \beta_{1,Fj} + 0.022 \beta_{2,Fj} + \dots + 0.022 \beta_{40,Fj} + 0.050 \beta_{41,Fj} + 0.07 \beta_{42,Fj}$$

Table 1 Barra E3 Model Risk Definitions

Descriptors in Risk Index	Risk Index
Beta times sigma Daily standard deviation High-low price Log of stock price Cumulative range Volume beta Serial dependence Option-implied standard deviation	Volatility
Relative strength Historical alpha	Momentum
Log of market capitalization	Size
Cube of log of market capitalization	Size Nonlinearity
Share turnover rate (annual) Share turnover rate (quarterly) Share turnover rate (monthly) Share turnover rate (five years) Indicator for forward split Volume to variance	Trading Activity
Payout ratio over five years Variability in capital structure Growth rate in total assets Earnings growth rate over the last five years Analyst-predicted earnings growth Recent earnings change	Growth
Analyst-predicted earnings-to-price Trailing annual earnings-to-price Historical earnings-to-price	Earnings Yield
Book-to-price ratio	Value
Variability in earnings Variability in cash flows Extraordinary items in earnings Standard deviation of analyst-predicted earnings-to-price	Earnings Variability
Market leverage Book leverage Debt to total assets Senior debt rating	Leverage
Exposure to foreign currencies	Currency Sensitivity
Predicted dividend yield	Dividend Yield
Indicator for firms outside US-E3 estimation universe	Non-Estimation Universe Indicator

Adapted from Table 8-1 in Barra (1998, pp. 71–73). Adapted with permission.

The nonfactor error term is measured in the same way as in the case of an individual stock. However, in a well-diversified portfolio, the nonfactor error term will be considerably less for the portfolio than for the individual stocks in the portfolio.

The same analysis can be applied to a stock market index because an index is nothing more than a portfolio of stocks.

RISK DECOMPOSITION

The real usefulness of a linear multifactor model lies in the ease with which the risk of a portfolio with several assets can be estimated. Consider a portfolio with 100 assets. Risk is commonly defined as the variance of the portfolio’s returns. So, in this case, we need to find the variance–covariance matrix of the 100 assets. That would require us to estimate 100 variances (one for each of the 100 assets) and 4,950 covariances among the 100 assets. That is, in all we need to estimate 5,050 values, a very difficult undertaking. Suppose, instead, that we use a three-factor model to estimate risk. Then, we need to estimate (1) the three factor loadings for each of the 100 assets (i.e., 300 values), (2) the six values of the factor variance–covariance matrix, and (3) the 100 residual variances (one for each asset). That is, we need to estimate only 406 values in all. This represents a nearly 90% reduction from having to estimate 5,050 values, a huge improvement. Thus, with well-chosen factors, we can substantially reduce the work involved in estimating a portfolio’s risk.

Multifactor risk models allow a manager and a client to decompose risk in order to assess the exposure of a portfolio to the risk factors and to assess the potential performance of a portfolio relative to a benchmark. This is the portfolio construction and risk control application of the model. Also, the actual performance of a portfolio relative to a benchmark can be assessed. This is the performance attribution analysis application of the model.

Barra suggests that there are various ways that a portfolio’s total risk can be decomposed

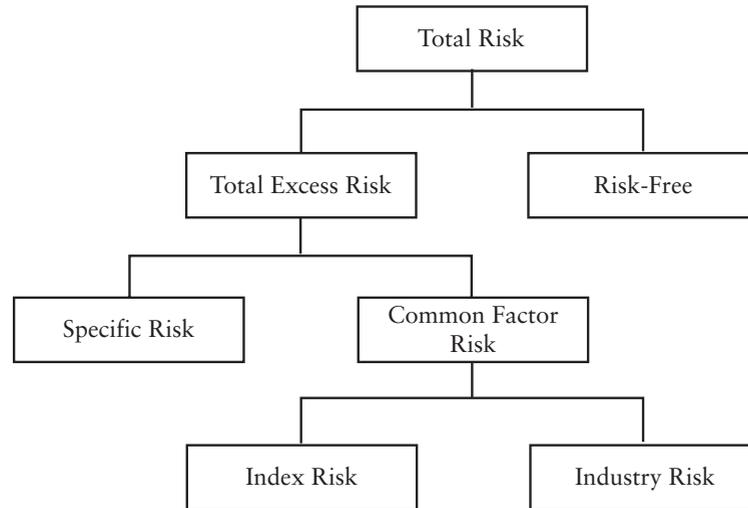

Figure 1 Total Risk Decomposition

Source: Figure 4.2 in Barra (1998, p. 34). Reprinted with permission.

when employing a multifactor risk model.³ Each decomposition approach can be useful to managers depending on the equity portfolio management that they pursue. The four approaches are (1) *total risk decomposition*, (2) *systematic-residual risk decomposition*, (3) *active risk decomposition*, and (4) *active systematic-active residual risk decomposition*.

In all of these approaches to risk decomposition, the total return is first divided into the risk-free return and the total excess return. The *total excess return* is the difference between the actual return realized by the portfolio and the risk-free return. The risk associated with the total excess return, called *total excess risk*, is what is further partitioned in the four approaches.

Total Risk Decomposition

There are managers who seek to minimize total risk. For example, a manager pursuing a long-short or market neutral strategy seeks to construct a portfolio that minimizes total risk. For such managers, total risk decomposition that breaks down the total excess risk into two components—*common factor risks* (e.g., capitalization and industry exposures) and *specific risk*—is useful. This decomposition is shown

in Figure 1. There is no provision for market risk, only risk attributed to the common factor risks and company-specific influences (i.e., risk unique to a particular company and therefore uncorrelated with the specific risk of other companies). Thus, the market portfolio is not a risk factor considered in this decomposition.

Systematic-Residual Risk Decomposition

There are managers who seek to time the market or who intentionally make bets to create a different exposure from that of a market portfolio. Such managers would find it useful to decompose total excess risk into systematic risk and residual risk as shown in Figure 2. Unlike in the total risk decomposition approach just described, this view brings market risk into the analysis. It is the type of decomposition where systematic risk is the risk related to a portfolio's beta.

Residual risk in the systematic-residual risk decomposition is defined in a different way from residual risk in the total risk decomposition. In the systematic-residual risk decomposition, residual risk is risk that is uncorrelated with the market portfolio. In turn, residual risk

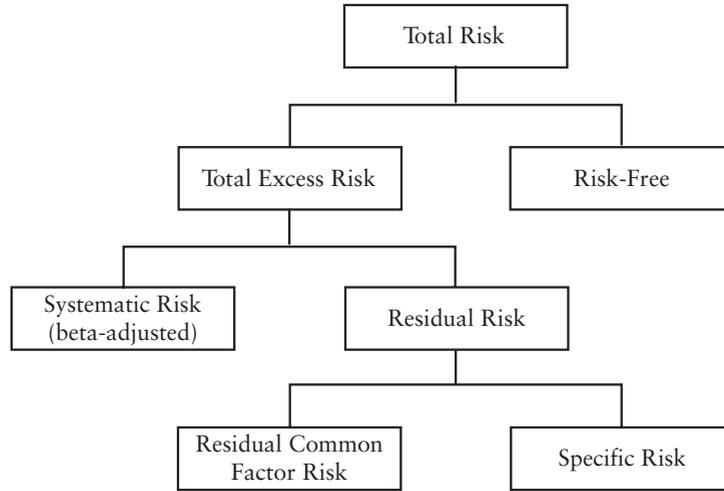

Figure 2 Systematic-Residual Risk Decomposition
 Source: Figure 4.3 in Barra (1998, p. 34). Reprinted with permission.

is partitioned into specific risk and common factor risk. Notice that the partitioning of risk described here is different from that in the arbitrage pricing theory model where all risk factors that could not be diversified away were referred to as “systematic risks.” In the discussion here, risk factors that cannot be diversified away are classified as market risk and common factor risk. Systematic risk can be diversified to a negligible level.

Active Risk Decomposition

The active risk decomposition approach is useful for assessing a portfolio’s risk exposure and actual performance relative to a benchmark index. In this type of decomposition, shown in Figure 3, the total excess return is divided into benchmark risk and active risk. Benchmark risk is defined as the risk associated with the benchmark portfolio.

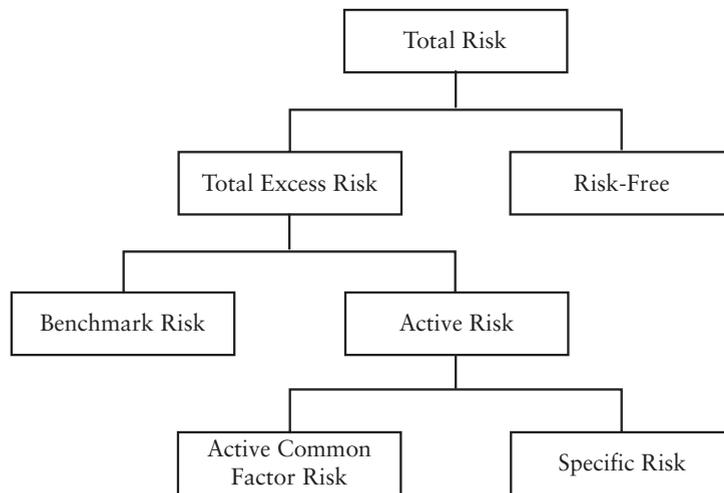

Figure 3 Active Risk Decomposition
 Source: Figure 4.4 in Barra (1998, p. 34). Reprinted with permission.

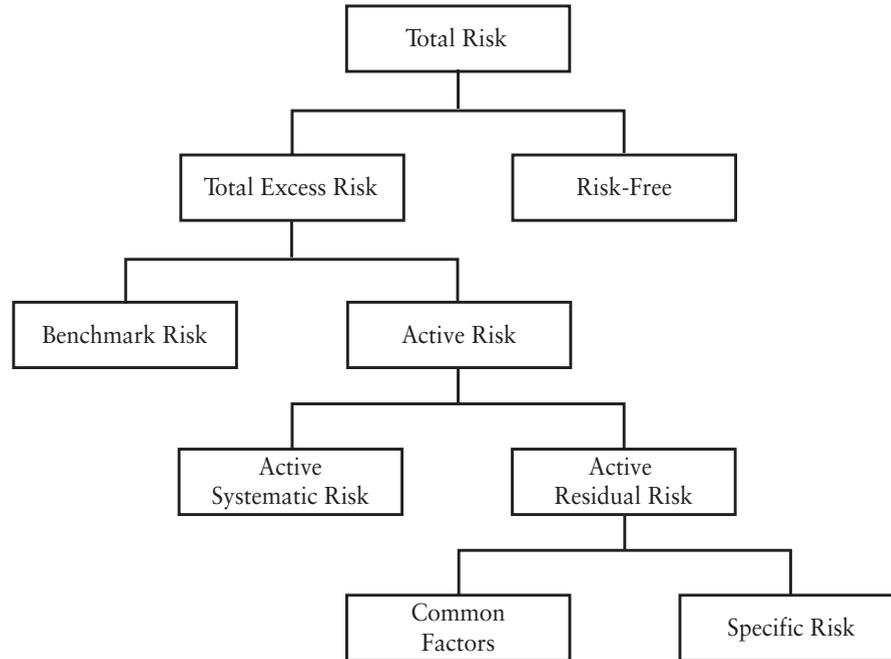

Figure 4 Active Systematic-Active Residual Risk Decomposition
Source: Figure 4.5 in Barra (1998, p. 37). Reprinted with permission.

Active risk is the risk that results from the manager's attempt to generate a return that will outperform the benchmark. Another name for active risk is tracking error. The active risk is further partitioned into common factor risk and specific risk. This decomposition is useful for managers of index funds and traditionally managed active funds.

Active Systematic-Active Residual Risk Decomposition

There are managers who overlay a market-timing strategy on their stock selection. That is, they not only try to select stocks they believe will outperform but also try to time the purchase of the acquisition. For a manager who pursues such a strategy, it will be important in evaluating performance to separate market risk from common factor risks. In the active risk decomposition approach just discussed, there is no market risk identified as one of the risk factors.

Since market risk (i.e., systematic risk) is an element of active risk, its inclusion as a source of risk is preferred by managers. When market risk is included, we have the active systematic-active residual risk decomposition approach shown in Figure 4. Total excess risk is again divided into benchmark risk and active risk. However, active risk is further divided into active systematic risk (i.e., active market risk) and active residual risk. Then active residual risk is divided into common factor risks and specific risk.

Summary of Risk Decomposition

The four approaches to risk decomposition are just different ways of slicing up risk to help a manager in constructing and controlling the risk of a portfolio and for a client to understand how the manager performed. Figure 5 provides an overview of the four approaches to carving up risk into specific/common factor, systematic/residual, and benchmark/active risks.

APPLICATIONS IN PORTFOLIO CONSTRUCTION AND RISK CONTROL

The power of a multifactor risk model is that given the risk factors and the risk factor sensitivities, a portfolio’s risk exposure profile can be quantified and controlled. The three examples below show how this can be done so that a manager can avoid making unintended bets. In the examples, we use the Barra E3 factor model.⁴

A fundamental multifactor risk model can be used to assess whether the current portfolio is consistent with a manager’s strengths. Table 2 is a list of the top 15 holdings of Portfolio ABC as of December 31, 2008. Table 3 is a summary risk decomposition report for the same portfolio. The portfolio had a total market value of \$5.4 billion, 868 holdings, and a predicted beta of 1.15. The risk report also shows that the portfolio had an active risk of 6.7%. This is its tracking error with respect to the benchmark, the S&P 500 index. Notice that nearly 93% of the active risk variance (which is 44.8) came from common factor variance (which is 41.6), and only a small proportion came from stock-specific risk variance (also known as asset selection variance, which is 3.2). Clearly, the manager of this portfolio had placed fairly large factor bets.

The top portion of Table 4 lists the factor risk exposures of Portfolio ABC relative to those of the S&P 500 index, its benchmark. The first column shows the exposures of the portfolio, and the second column shows the exposures of the benchmark. The last column shows the active exposure, which is the difference between the portfolio exposure and the benchmark exposure. The exposures to the risk index factors are measured in units of standard deviation,

while the exposures to the industry factors are measured in percentages. The portfolio had a high active exposure to the Volatility risk index factor. That is, the stocks in the portfolio were far more volatile than the stocks in the benchmark. On the other side, the portfolio had a low active exposure to the Size risk index. That is, the stocks in the portfolio were smaller than the benchmark average in terms of market capitalization. The lower portion of Table 4 is an abbreviated list of the industry factor exposures.

An important use of such risk reports is the identification of portfolio bets, both explicit and implicit. If, for example, the manager of Portfolio ABC did not intend to place the large bet on the Volatility risk index, then he has to make appropriate changes in the portfolio holdings until the active exposure to this factor is closer to zero.

Risk Control against a Stock Market Index

The objective of equity indexing is to match the performance of some specified stock market

index with little tracking error. To do this, the risk profile of the indexed portfolio must match the risk profile of the designated stock market index. Put in other terms, the factor risk exposure of the indexed portfolio must match as closely as possible the exposure of the designated stock market index to the same factors. Any differences in the factor risk exposures result in tracking error. Identification of any differences allows the indexer to rebalance the portfolio to reduce tracking error.

To illustrate this, suppose that an index manager has constructed a portfolio of 50 stocks to match the S&P 500 index. Table 5 lists the exposures to the Barra risk indexes of the 50-stock portfolio and the S&P 500 index. The last column in the exhibit shows the difference in exposures. The differences are very small except for the exposures to the Size risk index factor. Though not shown in this exhibit, there is a similar list of exposures to the 55 industry factors.

The illustration in Table 5 uses price data as of December 31, 2008. It demonstrates how a multifactor risk model can be combined with an optimization model to construct an indexed portfolio when a given number of holdings are sought. Specifically, the portfolio analyzed in the exhibit is the result of an application

in which the manager wants a portfolio constructed that matches the S&P 500 index with only 50 stocks and that minimizes tracking error. The optimization model uses the multifactor risk model to construct a 50-stock portfolio with a tracking error versus S&P 500 index of just 2.75%. Since this is the optimal 50-stock portfolio to replicate the S&P 500 index with a minimum tracking error risk, this tells the index manager that if he seeks a lower tracking error, then more stocks must be held. Note, however, that the optimal portfolio changes as time passes and prices move.

Tilting a Portfolio

Now let's look at how an active manager can construct a portfolio to make intentional bets. Suppose that a portfolio manager seeks to construct a portfolio that generates superior returns relative to the S&P 500 by tilting it toward low P/E stocks. At the same time, the manager does not want to increase tracking error significantly. An obvious approach may seem to be to identify all the stocks in the universe that have a lower than average P/E. The problem with this approach is that it introduces unintentional bets with respect to the other risk indexes.

Table 6 Factor Exposures of a Portfolio Tilted Toward Earnings Yield

^a Managed return.

^b Benchmark return (S&P 500).

^c Active return = Managed return - Benchmark return.

Instead, an optimization method combined with a multifactor risk model can be used to construct the desired portfolio. The necessary inputs to this process are the tilt exposure sought and the benchmark stock market index. Additional constraints can be placed, for example, on the number of stocks to be included in the portfolio. The Barra optimization model can also handle additional specifications such as forecasts of expected returns or alphas on the individual stocks.

In our illustration, the tilt exposure sought is toward low P/E stocks, that is, toward high earnings yield stocks (since earnings yield is the inverse of P/E). The benchmark is the S&P 500. We seek a portfolio that has an average earnings yield that is at least 0.5 standard deviations more than that of the earnings yield of the benchmark. We do not place any limit on the number of stocks to be included in the portfolio. We also do not want the active exposure to any other risk index factor (other than earnings yield) to be more than 0.1 standard deviations in magnitude. This way we avoid placing unintended bets. While we do not report the holdings of the optimal portfolio here, Table 6 provides an analysis of that portfolio by comparing the risk exposure of the 50-stock optimal portfolio to that of the S&P 500. Though

not shown in Table 6, there is a similar list of exposures to the 55 industry factors.

KEY POINTS

- There are three types of multifactor equity risk models that are used in practice: statistical, macroeconomic, and fundamental. The most popular is the fundamental model.
- A multifactor equity risk model assumes that stock returns (and hence portfolio returns) can be explained by a linear model with multiple factors, consisting of “risk index” factors such as company size, volatility, momentum, and so on, and “industry” factors. The portion of the stock return that is not explained by this model is the stock-specific return.
- The risk index factors are measured in standard deviation units, while the industry factors are measured in percentages.
- The real usefulness of a linear multifactor model lies in the ease with which the risk (i.e., the volatility) of a portfolio with several assets can be estimated. Instead of estimating the variance-covariance matrix of its assets, it is only necessary to estimate the portfolio’s factor exposures and the variance-covariance matrix of the factors, a computationally much easier task.

- The variance-covariance matrix of the factors and the factor exposures of stocks are calculated based on a mix of historical and current data and are updated periodically.
 - Total risk of a portfolio can be decomposed in several ways. The partitioning method chosen is based on what is useful given the manager's strategy. The active risk decomposition method is useful for managers of index funds and traditionally managed active funds.
 - The level of active risk of a portfolio and the split of the tracking error variance between the common factor portion and the stock-specific portion are useful in assessing if the portfolio is constructed in a way that is consistent with the manager's strengths.
 - The list of active factor exposures of a portfolio helps the manager identify its bets, both explicit and implicit. If a manager discovers some unintended bets, then the portfolio can be rebalanced so as to minimize such bets.
 - Using a multifactor risk model and an optimization model, a portfolio that has the minimum active risk relative to its benchmark for a given number of assets held can be constructed. This application is useful for passive managers.
- Similarly, a manager can construct a portfolio that tilts toward a specified factor and has no material active exposure to any other factor. This application is useful for active managers.

NOTES

1. For a discussion of the different types of factor models, see Connor (1995).
2. For a more detailed description of each descriptor, see Appendix A in Barra (1998). A listing of the 55 industry groups is provided in Table 4 in this entry.
3. See Chapter 4 in Barra (1998). The discussion to follow in this section follows that in the Barra publication.
4. The illustrations were created by the authors based on applications suggested in Chapter 6 of Barra (1996).

Multifactor Fixed Income Risk Models and Their Applications

ANTHONY LAZANAS, PhD
Managing Director, Barclays

ANTÓNIO BALDAQUE DA SILVA, PhD
Managing Director, Barclays

RADU GĂBUDEAN, PhD
Vice President, Barclays

ARNE D. STAAL, PhD
Director, Barclays

Abstract: Multifactor risk models seek to estimate and characterize the risk of a portfolio, either in absolute value or when compared against a benchmark. Risk is typically decomposed into a systematic and an idiosyncratic component. Systematic risk captures the exposures the portfolio has to broad risk factors, such as interest rates or spreads. This risk is driven by the exposure of the portfolio to these risk factors, their volatility, and the correlation between these different sources of risk. Idiosyncratic risk captures the uncertainty associated with the particular issuers in the portfolio. Idiosyncratic risk is diversifiable by spreading the exposure to a large number of individual issuers. Multifactor risk models allow for the decomposition of the total risk by risk factor (or sets of risk factors). If the factors are economically meaningful, the risk model can provide relevant intuition regarding the major variables influencing the volatility of the portfolio and be a useful tool in portfolio construction.

In this entry, we discuss risk modeling construction and applications to fixed income portfolios. Although they share a similar framework, multifactor models in fixed income use different building blocks and provide a different analysis of the risk of a portfolio.

When analyzing their holdings, portfolio managers constantly monitor their exposures, typically net of a benchmark: What is the portfolio net duration? How risky is the overweight to credit? How does it relate to the exposure to mortgages? What is the exposure to specific

The authors would like to thank Andy Sparks for his valuable comments.

issuers? Even when portfolio holdings and exposures are well known, portfolio managers increasingly rely on quantitative techniques to translate this information into a common risk language. *Risk models* can present a coherent view of the portfolio, its exposures, and how they correlate to each other. They can quantify the risk of each exposure and its contribution to the overall risk of the portfolio.

Fixed income securities are exposed to many different types of risk. Multifactor risk models in this area capture these risks by first identifying common sources along different dimensions, the systematic risk factors. All risk not captured by systematic factors is considered idiosyncratic or security-specific. Typically, fixed income systematic risk factors are divided into two sets: those that influence securities across asset classes (e.g., yield curve risk) and those specific to a particular asset class (e.g., prepayment risk in securitized products).

There are many ways to define systematic *risk factors*. For instance, they can be defined purely by statistical methods, observed in the markets, or estimated from asset returns. In fixed income, the standard approach is to use pricing models to calculate the analytics that are the natural candidates for risk factor loadings (also called sensitivities). In this setting, the risk factors are estimated from cross-sectional asset returns. This is the approach taken in the Barclays Global Risk Model,¹ which is the model used for illustration throughout this entry.

In this risk model, the forecasted risk of the portfolio is driven by both a systematic and an idiosyncratic (also called specific, nonsystematic, and concentration) component. The forecasted systematic risk is a function of the mismatch between the portfolio and the benchmark in the exposures to the risk factors, such as yield curve or spreads. The exposures are aggregated from security-level analytics. The systematic risk is also a function of the volatility of the risk factors, as well as the correlations between them. In this setting, the correlation

of returns across securities is driven by the correlation of systematic risk factors these securities load on. As the model uses security-level returns and analytics to estimate the factors, we can recover the idiosyncratic return for each security. This is the return net of all systematic factors. The model uses these idiosyncratic returns to estimate rich specifications for the idiosyncratic risk.

APPROACHES USED TO ANALYZE RISK

In what follows, we turn to the analysis of the risk of a particular portfolio, going through the different approaches typically used. Specifically, consider a portfolio manager that is benchmarked against the Barclays US Aggregate Index. Moreover, suppose she believes interest rates are coming down—so she wants to be long duration—and that she wants some extra yield in her portfolio—meaning investing in bonds with relatively higher spreads. Finally, let us assume that she is mandated to keep the difference between the returns of the portfolio and the benchmark at around 15 basis points, on a monthly basis. Therefore, she has to track a benchmark, but is allowed to deviate from it up to a point in order to express views that hopefully lead to superior returns. A portfolio manager with such a mandate is called an enhanced indexer. The amount of deviation allowed is called the risk budget (15 basis points in our example) and can be quantified using a risk model. The risk model produces an estimate of the volatility of the difference of the portfolio and benchmark returns, called *tracking error volatility* (TEV). (In this entry, we refer to TEV, risk, and the standard deviation of the portfolio net returns interchangeably.) The portfolio manager should keep the TEV at a level equal to or less than her risk budget. For illustration, we construct a portfolio with 50 securities that is consistent with the portfolio manager's views

Table 1 Market Weights for Portfolio and Benchmark

Asset Class	Portfolio	Benchmark	Difference
Total	100.0	100.0	0.0
Treasury	30.2	32.1	-1.9
Government-related	5.8	12.3	-6.5
Corporate industrials	9.0	9.7	-0.7
Corporate utilities	2.9	2.1	0.8
Corporate financials	18.6	6.4	12.2
MBS agency	28.4	34.1	-5.8
ABS	0.0	0.3	-0.3
CMBS	5.2	3.1	2.1

and risk budget and analyze it throughout this entry.

Market Structure and Exposure Contributions

The first level of analysis that any portfolio manager usually performs is to compare the portfolio holdings in terms of market value with the holdings from the benchmark. For instance, Table 1 shows that the composition of the portfolio has several important mismatches when compared with the benchmark. The portfolio is underweighted in Treasuries and government-related securities by 8.4%. This is compensated with an overweight of 12.3% in corporates, especially in the financials sector. Other mismatches include an underweight in mortgage-backed securities (MBS) (-5.8%) and an overweight in commercial mortgage-backed securities (CMBS) (+2.1%).

Interestingly, for an equity manager, this kind of information—for example, applied to the different industries or sectors of the portfolio—would be of paramount importance to the analysis of the risk of her portfolio. For a fixed income portfolio, this is not the case. Although important, this analysis tells us very little about the true active exposures of a fixed income portfolio. What if the Treasuries in the portfolio have significantly longer duration than those in the benchmark—would we

Table 2 Aggregate Analytics

Analytics	Portfolio	Benchmark	Difference
Duration	4.55	4.30	0.25
Spread duration	4.67	4.56	0.11
Convexity	-0.15	-0.29	0.13
Vega	-0.02	-0.01	-0.01
Spread	157	57	100

be really “short” in this asset class? What if the spreads from financials in the portfolio are much smaller than those in the benchmark—the weight mismatch that important?

To answer this kind of questions, we turn to another typical dimension of analysis—the exposure of the portfolio to major sources of risk. An example of such a risk exposure is the duration of the portfolio. Other exposures typically monitored are the spread duration, convexity, spread level, and vega (if the portfolio has many securities with optionality, such as mortgages or callable bonds).

Table 2 shows these analytics at the aggregate level for our portfolio, benchmark, and the difference between the two. In particular, we can see that the portfolio is long duration (+0.25 years), consistent with the forecast the manager has regarding yield curve moves. In terms of spread duration, the mismatch is somewhat smaller. We can also see that the portfolio has significantly lower negative convexity than the benchmark (-0.15 versus -0.29), probably coming from the smaller weight MBS securities have in the portfolio. The portfolio has also a higher negative vega, but the number is reasonably small for both universes. Finally, the portfolio has significantly higher spreads (100 basis points) than the benchmark. This mismatch is consistent with the manager’s goal of having a higher yield in her portfolio, when compared with the benchmark.

The analysis in the Tables 1 and 2 can be combined to deliver a more detailed picture of where the different exposures are coming from. Table 3 shows that analysis for the duration of the portfolio. This exhibit shows that the majority of the mismatch in duration contribution

Table 3 Duration Contribution per Asset Class

Duration Contribution	Portfolio	Benchmark	Difference
Total	4.55	4.30	0.25
Treasury	1.92	1.71	0.21
Government-related	0.40	0.49	-0.09
Corporate	1.31	1.19	0.11
Securitized	0.92	0.90	0.02

(market-weighted duration exposures) comes from the Treasury component of our portfolio (+0.21). Interestingly, even though we are short in Treasuries, we are actually long in duration for that asset class. This means that our Treasury portfolio will be negatively impacted, when compared with the benchmark, by an increase in interest rates. Because we are short in Treasuries, this result must mean that our Treasury portfolio is longer in duration than the Treasury component of the benchmark. Conversely, we have a relatively small contribution to excess duration coming from our very large overexposure to corporates. This means that on average the corporate bonds in the portfolio are significantly shorter in duration than those in the benchmark.

Adding Volatility and Correlations into the Analysis

The analysis above gives us some basic understanding of our exposures to different kinds of risk. However, it is still hard to understand how we can compare the level of risk across these different exposures. What is more risky, the long duration exposure of 0.25 years, or the extra spread of 100 basis points? How can we quantify how serious is the vega mismatch on my portfolio? Specifically, the risk of the portfolio is a function of the exposures to the risk factors, but also of how volatile (how “risky”) each of the factors is. So to enhance the analysis we bring volatilities into the picture. Table 4 shows the outcome of this addition to our example. In

Table 4 Isolated Risk per Category

Risk Factors Categories	Risk
Curve	8.5
Volatility	1.7
Spread government-related	3.0
Spread corporate	5.1
Spread securitized	3.0

particular, it displays the risk of the different exposures of the portfolio in isolation (that is, if the only active imbalances were those from that particular set of risk factors).

For example, in Table 4 one can see that if the only active weight in the portfolio were the mismatch in the yield curve exposures, the risk of the portfolio would be 8.5 basis points per month. By adding volatilities into the analysis, we can now quantify that the mismatch of +0.25 years in duration “costs” the portfolio 8.5 basis points per month of extra volatility, when taken in isolation.² Similarly, if the only mismatch were the exposure to corporate spreads, the risk of the portfolio would be 5.1 basis points. Interestingly, we also see that both government-related and securitized sectors have nontrivial risk, despite having smaller imbalances in terms of market weights. By bringing volatilities into the analysis, we can now compare and quantify the impact of each of the imbalances in the portfolio.

For future reference, consider the volatility of the portfolio if all these sources of risk were independent (e.g., correlations were zero). That number would be 10.9 basis points per month.³ Of course, this scenario is unrealistic, as these sources of risk are not independent. Also, this analysis does not allow us to understand the interplay between the different imbalances. For instance, we know that the isolated risk associated with the curve is 8.5. But this value can be achieved both by being long or short duration. So the isolated number does not allow us to understand the impact of the curve imbalance to the total risk of the portfolio. The net impact certainly depends on the sign of the imbalance. For instance, if the long exposure in

Table 5 Correlated Risk per Category

Risk Factors Categories	Risk
Total	9.3
Curve	5.9
Volatility	0.1
Spread government-related	0.1
Spread corporate	2.4
Spread securitized	0.7

curve is diversified away by a long exposure in credit (due, for instance, to negative correlation between rates and credit spreads), a symmetric (short) curve exposure would add to the risk of the long exposure in credit. The risk is clearly smaller in the first case.

To alleviate these shortcomings, we bring correlations into the picture. They allow us to understand the net impact of the different exposures to the portfolio’s total risk and to detect potential sources of diversification among the imbalances in the portfolio. Table 5 reports the contribution of each of the risk factor groups to the total risk, once all correlations are taken into account. The total risk (9.3 bps/month) is smaller than the zero-correlation risk calculated before (10.9 bps/month) due to generally negative correlations between the curve and the spread factors. The exhibit also allows us to isolate the main sources of risk as being curve (5.9 bps/month) and credit spreads (2.4 bps/month), in line with the evidence from the earlier analysis. In particular, the risk of the government-related and securitized spreads is significantly smaller once correlations are taken into account.

The difference in analysis between the isolated and correlated risks reported in Tables 4 and 5 deserves a bit more discussion. For simplicity, assume there are only two sources of risk in the portfolio—yield curve (Y) and spreads (S). The total systematic variance of the portfolio (P) can be illustrated as follows:

$$\begin{aligned} VAR(P) &= VAR(Y + S) \\ &= VAR(Y) + VAR(S) + 2COV(Y, S) \\ &= Y \times Y + S \times S + 2(Y \times S) \end{aligned}$$

where we use the product (\times) to represent variances and covariances. Another way to represent this summation is using the following matrix:

$$\begin{bmatrix} Y \times Y & Y \times S \\ Y \times S & S \times S \end{bmatrix}$$

The sum of the four elements in the matrix is the variance of the portfolio. The isolated risk (in standard deviation units) reported in Table 4 is the square root of the diagonal terms. So the isolated risk due to spreads is represented as

$$Risk_{Spreads}^{Isolated} = \sqrt{S \times S}$$

It would be a function of the exposure to all spread factors, the volatilities of all these factors, and the correlations among them.

The correlated risk reported in Table 5 is

$$Risk_{Spreads}^{Correlated} = [Y \times S + S \times S] / \sqrt{VAR(P)}$$

that is, we sum all elements in the row of interest (row 1 for Y , row 2 for S) from the matrix above, and normalize it by the standard deviation of the portfolio. This statistic (1) takes into account correlations and (2) ensures that the correlated risks of all factors add up to the total risk of the portfolio ($Risk_{Curve}^{Correlated} + Risk_{Spreads}^{Correlated} = \sqrt{VAR(P)} = STD(P)$).⁴

The generic analysis we just performed constitutes the first step into the description of the risk associated with a portfolio. The analysis refers to categories of risk factors (such as “curve” or “spreads”). However, a factor-based risk model allows for a significantly deeper analysis of the imbalances the portfolio may have. Each of the risk categories referred to above can be described with a rich set of detailed risk factors. Typically in a fixed income factor model, each asset class has a specific set of risk factors, in addition to the potential set of factors common to all (e.g., curve factors). These asset-specific risk factors are designed to capture the particular sources of risk the asset class is exposed to. In the following section, we

go through a *risk report* built in such a way, emphasizing risk factors that are common or particular to the different asset classes. Along the way, we demonstrate how the report offers insights from both a risk management and a *portfolio construction* perspective.

A Detailed Risk Report

In this section, we continue the analysis of the portfolio introduced previously, a 50-bond portfolio benchmarked against the Barclays US Aggregate Index. The report package we present was generated using POINT[®], Barclays cross-asset portfolio analysis and construction system, and gives a very detailed picture of the risk embedded in the portfolio. The package is divided into four types of reports: summary reports, factor exposure reports, issue/issuer level reports, and scenario analysis reports. Some of the information we reviewed earlier can be thought of as summary reports.

Summary Report

Table 6 illustrates a typical risk summary statistics report. It shows that the portfolio has 50 positions, but from only 27 issuers. This number implies limited ability to diversify idiosyncratic risk, as we will see below. The report confirms that the portfolio is long duration (OAD of 4.55 years versus 4.30 years for the benchmark) and has higher yield (yield to worst of 3.71% versus 2.83% for the benchmark) and coupon (4.73% versus 4.46% for the benchmark).

The table also reports that the total volatility of the portfolio (163.3 bps/month) is higher than that of the benchmark (158.1 bps/month). This is not surprising: longer duration, higher spread and less diversification all tend to increase the volatility of a portfolio. Because of its higher volatility, we refer to the portfolio as riskier than the benchmark. Looking into the different components of the portfolio's total volatility, the table reports that the idiosyncratic volatility of the portfolio is significantly smaller

Table 6 Summary Statistics Report

	Portfolio	Benchmark	
A. Parameter			
Positions	50	8,191

Convexity	-0.15	-0.29	0.13
C. Volatility			
	Portfolio	Benchmark	TEV
Systematic	162.9	158.0	9.3
Idiosyncratic	11.1	5.6	10.1
Total	163.3	158.1	13.7
D. Portfolio Beta			
			1.03

than that of the systematic (11.1 bps/month versus 162.9 bps/month, respectively). This is also expected from a portfolio of investment-grade bonds. Given the fact that by construction the systematic and idiosyncratic components of risk are independent, we can calculate the total volatility of the portfolio as

$$TEV_{PTF} = \sqrt{162.9^2 + 11.1^2} = 163.3$$

There are two interesting observations regarding this number: first, the total volatility is smaller than the sum of the volatilities of the two components. This is the diversification benefit that comes from combining independent sources of risk. Second, the total volatility is very close to the systematic one. This may suggest that the idiosyncratic risk is irrelevant. That is an erroneous and dangerous conclusion. In particular, when managing against a benchmark, the focus should be on the net exposures and risk, not on their absolute

Table 7 Factor Partition—Risk Analysis

Risk Factor Group	Isolated TEV	Contribution to TEV	Liquidation Effect on TEV	TEV Elasticity (%)
Total	13.7	13.7	-13.7	1.0
Systematic risk	9.3	6.3	-3.6	0.5
Curve	8.5	4.0	-1.5	0.3
Volatility	1.7	0.1	0.0	0.0
Government-related spreads	3.0	0.1	0.2	0.0
Corporate spreads	5.1	1.6	-0.7	0.1
Securitized spreads	3.0	0.5	-0.2	0.1
Idiosyncratic risk	10.1	7.4	-4.4	0.5

counterparts. In Table 6 the total TEV is reported as 13.7 bps/month. This means that the model forecasts the portfolio return to be typically no more than 14 bps/month higher or lower than the return of the benchmark. This number is in line with the risk budget of our manager. The exhibit also reports idiosyncratic TEV of 10.1 bps/month, which is greater than the systematic TEV (9.3). When measured against the benchmark, our major source of risk is idiosyncratic, contrary to the conclusion one could draw by looking only at the portfolio's volatility. The TEV of our portfolio is also bigger than the difference between the volatilities of the portfolio and benchmark. Again, this is not surprising: The volatility depends on the absolute exposures, while the TEV measures imbalances between these absolute exposures from the portfolio and the benchmark. For the TEV what matters most is the correlation between these absolute exposures. Depending on this correlation, the TEV may be smaller or bigger than the difference in volatilities.

Finally, the report estimates the portfolio to have a beta of 1.03 to the benchmark. This statistic measures the co-movement between the portfolio and the benchmark. We can read it as follows: The model forecasts that a movement of 10 bps in the benchmark leads to a movement of 10.3 bps in the portfolio in the same direction. Note that a beta of less than one does not mean that the portfolio is less risky than the benchmark. In the limit, if the portfolio and benchmark are uncorrelated, the port-

folio beta is zero but obviously that does not mean that the portfolio has zero risk. Finally, one can compute many different "betas" for the portfolio or subcomponents of it.⁵ A simple and widely used one is the "duration beta," given by the ratio of the portfolio duration to that of the benchmark. In our case this ratio is $4.55/4.30 = 1.06$. This implies that the portfolio has a return from yield curve movements around 1.06 times larger than that of the benchmark. This beta is larger than the portfolio beta (1.03), meaning that net exposures to other factors (e.g., spreads) "hedge" the portfolio's curve risk.

This first summary report (Table 6) allows us to get a glimpse into the risk of the portfolio. However, we want to know in more detail what the source of this risk is. To do that, we turn to the next two summary reports. In the first, risk is partitioned across different groups of risk factors. In the second, the partition is across groups of securities/asset classes.

Table 7 shows four different statistics associated with each set of risk factors. The first two were somewhat explored in Tables 4 and 5.⁶ The exhibit reports in the first column the isolated TEV, that is, the risk associated with that particular set of risk factors only. We see that in an isolated analysis, the systematic and idiosyncratic risks are balanced, at 9.3 and 10.1 respectively. The report also shows the isolated risk associated with the major components of systematic risk. As discussed before, all components of systematic risk have nontrivial isolated risk, but only curve and credit spreads

Table 8 Security Partition—Risk Analysis I

Security Partition Bucket	NMW (%)	Contribution to TEV		
		Systematic	Idiosyncratic	Total
Total	0.0	6.3	7.4	13.7
Treasuries	-2.0	2.9	0.2	3.1
Government agencies	-5.4	0.5	0.4	0.9
Government nonagencies	-1.0	-1.4	0.1	-1.3
Corporates	12.4	3.4	4.3	7.7
MBS	-5.8	0.9	0.8	1.7
ABS	-0.3	0.0	0.0	0.0
CMBS	2.1	0.0	1.6	1.6

are significant when we look into the *contributions* to TEV. If we look across factors, the major contributors are idiosyncratic risk, curve, and credit spreads. Other systematic exposures are relatively small.

Another look into the correlation comes when we analyze the liquidation effect reported in the table. This number represents the change in TEV when we completely hedge that particular group of risk factors. For instance, if we hedge the curve component of our portfolio, our TEV drops by 1.5 bps/month, from 13.7 to 12.2. One may think that the drop is rather small, given the magnitude of isolated risk the curve represents. However, if we hedge the curve, we also eliminate the beneficial effect the negative correlation between curve and spreads have on the overall risk of the portfolio. Therefore, we have a more limited impact when hedging the curve risk. In fact, for this portfolio we see that hedging any particular set of risk factors has a limited effect in the overall risk.

The TEV elasticity reported in the last column gives another perspective into how the TEV in the portfolio changes when we change the risk loadings. Specifically, it tells us what the percentage change in TEV would be if we changed our exposure to that particular set of factors by 1%. We can see that if we reduce our exposure to corporate spreads by 1%, our TEV would decrease by 0.1%.

We perform a similar analysis in Table 8, but applied to a security partition. That is, instead of looking at individual sources of risk (e.g.,

curve) across all securities, we now aggregate all sources of risk within a security and report analytics for different groups of these securities (e.g., subportfolios). In particular, Table 8 reports the results by asset class. We can see that the majority of risk (7.7 bps/month) is coming from the corporate component of the portfolio.⁷ Corporates are also the primary contributors to the portfolio's systematic and idiosyncratic components of risk. This is not surprising, given the portfolio's large net market weight (NMW) to this sector. There are two other important sources of risk. The first is the Treasuries subportfolio, with 3.1 bps/month of risk. This risk comes mainly from the mismatch in duration. The second comes from the idiosyncratic risk of the CMBS component of the portfolio. Even though the NMW and systematic risk are not significant for this asset class, the relatively small number of (risky) CMBS positions in the portfolio causes it to have significant idiosyncratic risk (three securities in the portfolio versus 1,735 in the index). Since the portfolio manager is trying to replicate a very large benchmark with only 50 positions, she has to be very confident in the issuers selected. This report highlights the significant name risk the portfolio is exposed to.

Table 9 completes the analysis, reporting other important risk statistics about the different asset classes within the portfolio. These statistics mimic the analysis done in terms of risk factor partitions in Table 7, so we will not repeat their definitions. We focus on the

Table 9 Security Partition—Risk Analysis II

Security Partition Bucket	Isolated TEV	Liquidation Effect on TEV	TEV Elasticity (%)
Total	13.7	−13.7	1.0
Treasuries	7.4	−1.1	0.2
Government agencies	9.1	2.0	0.1
Government nonagencies	6.7	2.7	−0.1
Corporates	15.2	0.6	0.6
MBS	5.8	−0.5	0.1
ABS	1.1	0.1	0.0
CMBS	5.1	−0.7	0.1

numbers. In particular, the isolated TEV from the corporate sector is 15.2 bps/month, higher than the total risk of the portfolio. This means that the exposures to the other asset classes, on average, hedge our credit portfolio. The exhibit also reports that the agencies isolated risk is very large. This is due to the large negative net exposure (−5.4%) we have to this asset class. But the risk is fully hedged by the other exposures of the portfolio (e.g., long exposure to credit or long duration on Treasuries), so overall the risk contribution of this asset class is small, as previously discussed. We can even take the analysis a bit further: Table 9 shows us through the liquidation effect that if we eliminate the imbalance the portfolio has on agencies, we actually would increase the total risk of the portfolio by 2.0 bps/month. In short, we would be eliminating the hedge this asset class provides to the global portfolio, therefore increasing its risk. The exposures to this asset class were clearly built to counteract other exposures in the portfolio. Finally, Table 9 also reports the TEV elasticity of the different components of the portfolio. This number represents the percentage change in TEV if the NMW to that sub-portfolio changes by 1%, so we need to read the numbers with an opposite sign if the NMW is negative. In particular, if we increase the weight of the agency portfolio in absolute value (making it “more short”) by 1%, we would actually increase the TEV by 0.1%. This result shows that

the position in agencies provides hedging “on average,” but marginally it is already increasing the risk of the portfolio. In other words, the hedging went beyond its optimal value.

This set of summary reports gives us a very clear picture of the major sources of risk and how they relate to each other. In what follows, we focus on the more detailed analysis of the individual systematic sources of risk.

Factor Exposure Reports

At the heart of a multifactor risk model is the definition of the set of systematic factors that drive risk across the portfolio. As described above, there are different types of risk a fixed income portfolio is exposed to. In what follows, we focus on the three major types: curve, credit, and prepayment risk. Specifically in what regards the latter two, we use the credit and MBS component of the portfolio, respectively, to illustrate how to measure risks along these dimensions. Moreover, to keep the example simple, we show only a partial view of all relevant factors for these sources of risk. Later in this section we refer briefly to other sources of risk a fixed income portfolio may be exposed to.

Curve Risk As the previous analysis shows (e.g., Table 7), curve is the major source of risk in our portfolio. This kind of risk is embedded in virtually all fixed income securities (exceptions are, for instance, floaters and distressed securities), therefore mismatches are very penalizing.

When analyzing curve risk, we should use the curve of reference we are interested in. Depending on the portfolio and circumstances, this is typically the government or swap curve.⁸ In calm periods, the behavior of the swap curve tends to match that of the government curve. However, during liquidity crises (e.g., the Russian crisis in 1998 or the credit crisis in 2008), they can diverge significantly. To capture these different behaviors adequately, we analyze curve risk using the following decomposition: For government products, the curve

risk is assessed using the government curve. For all other products in our portfolio (that usually trade off the swap curve), this risk is measured using both the Treasury curve and swap spreads (i.e., the spreads between the swap and the government curve). Other decompositions are also possible.

The risk associated with each of these curves can be described by the exposure the portfolio has to different points along the curve and how volatile and correlated the movement in these points of the curve are. A additional convexity term is sometimes used to capture the non-linear components of curve risk. For a typical portfolio, a good description of the curve can be achieved by looking at a relatively small number of points along the curve (called key rates), for example, 6-month, 2-year, 5-year, 10-year, 20-year, and 30-year. An alternative set of factors used to capture yield curve risk can be defined using statistical analysis of the historical realizations of the various yield curve points. The statistical method used most often is called principal component analysis (PCA). This method defines factors that are statistically independent of each other. Typically three or four such factors are sufficient to explain the risk associated with changes of yields across the yield curve. PCA analysis has several shortcomings and must be used with caution. Using a larger set of economic factors, such as the key rate points described above, is more intuitive and captures the risk of specialized portfolios better. In our analysis, we follow the key rates approach.

Table 10 details the risk in our portfolio associated with the US Treasury curve. It starts by describing all risk factors our portfolio or benchmark load on. As discussed above, we identify the six key rate (KR) points in the curve plus the convexity term as the risk factors associated with US Treasury risk. They are described in the first column of panel A in the exhibit. They measure the risk associated with moves in that particular point in the curve. Exposure to these risk factors is measured by the key rate dura-

tions (KRD) for each of the six points. The description of the loading is in the second column of the exhibit, while its value for the portfolio, benchmark, and the difference is displayed in the next columns. Key rate durations are also called partial durations, as they add up to approximately the duration of the portfolio. Their loadings are constructed by aggregating partial durations across (virtually) all the securities. For instance, for our portfolio, the sum of the key rate durations is $0.14 + 0.86 + 1.30 + 0.77 + 1.02 + 0.47 = 4.56$, very close to the total duration of our portfolio.

Looking at the table, we see significant mismatches in the duration profiles between our portfolio and its benchmark, namely at the 10-year and 20-year points on the curve. Specifically, we are short 0.41 years at the 10-year point and long 0.53 years at the 20-year point. How serious is this mismatch? Looking at the factor volatility column, it can be seen that these points on the curve have been very volatile at around 40 bps/month. If we interpret this volatility as a typical move, the first two columns of panel B show us the potential impact of such a movement in the return of our portfolio, net of benchmark. For instance, a typical move up (+44.2 bps/month) in the 10-year point of the Treasury curve, when considered in isolation, will deliver a positive net return of 15.9 bp.⁹ In isolation, the positive impact is expected because we are short that point of the curve. More interesting may be the correlated number on the exhibit. It states the return impact but in a correlated fashion. In the scenario under analysis, a movement in the 10-year point will almost certainly involve a movement of the neighboring points in the curve. So, contrary to the positive isolated effect documented above, the correlated impact of a change up in the 10-year point is actually negative, at -5.0 bps. This result is in line with the overall positive duration exposure the portfolio has: General (correlated) movements up in the curve have negative impact in the portfolio's performance.¹⁰ Finally, and broadly

Table 10 Treasury Curve Risk

A. Exposures and Factor Volatility					
Factor Name	Units	Exposure			Factor Volatility
		Portfolio	Benchmark	Net	
USD 6M key rate	KRD (Yr)	0.14	0.15	-0.01	36.0
USD 2Y key rate	KRD (Yr)	0.86	0.70	0.15	38.0
USD 5Y key rate	KRD (Yr)	1.30	1.25	0.05	44.3
USD 10Y key rate	KRD (Yr)	0.77	1.13	-0.36	44.2
USD 20Y key rate	KRD (Yr)	1.02	0.53	0.49	39.6
USD 30Y key rate	KRD (Yr)	0.47	0.53	-0.06	39.7
USD convexity	OAC	-0.15	-0.29	0.13	8.4

B. Other Risk Statistics				
Factor Name	Return Impact of a Typical Move		Marginal Contribution to TEV	TEV Elasticity (%)
	Isolated	Correlated		
USD 6M key rate	0.5	-2.4	6.3	0.0
USD 2Y key rate	-5.8	-4.5	12.2	0.1
USD 5Y key rate	-2.0	-4.5	14.5	0.0
USD 10Y key rate	15.9	-5.0	15.9	-0.4
USD 20Y key rate	-19.5	-5.2	14.9	0.5
USD 30Y key rate	2.5	-5.2	14.8	-0.1
USD convexity	1.1	2.0	1.2	0.0

speaking, the (negative of the) ratio of the correlated impact to the factor volatility gives us the model-implied partial empirical duration of the portfolio. For instance, if we focus on the 10-year point, we get $-(-5.0/44.2) = 0.11$. This smaller empirical duration is typical in portfolios with spread exposure. The spread exposure tends to empirically hedge some of the curve exposure, given the negative correlation between these two sources of risk. Finally, the exhibit shows the risk associated with convexity. We can see that the benchmark is significantly more negatively convex, so the portfolio is less responsive than the benchmark to higher order changes in the yield curve.

There are many other statistics of interest one can analyze regarding the Treasury curve risk of the portfolio. Portfolio managers frequently have questions such as: If I want to reduce the risk of my portfolio by manipulating my Treasury curve exposure, what should I change? What is the most effective move? By how much would my risk actually change? The

statistics reported in the columns “Marginal Contribution to TEV” and “TEV Elasticity (%)” of panel B are typically used to answer these questions. Regarding the marginal contributions, the 10-year point has the largest value, indicating that an increase (reduction) of one unit of exposure (in this case one year of duration) to the 10-year point leads to an increase (reduction) of around 16 bps in the TEV.¹¹ In other words, if we want to reduce risk by manipulating our exposure to the yield curve, the 10-year point seems to present the fastest track. In addition, the exhibit shows that all Treasury risk factors are associated with positive marginal contributions. This means that an increase in the exposure to any of these factors increases the risk (TEV) of the portfolio. This conclusion holds, even for factors for which we have negative exposure (e.g., the 10-year key rate). The reason behind this result is our overall long duration exposure. If we add exposure to it, regardless of the specific point where we add it, we extend our duration

Table 11 Swap Spread (SS) Risk

Factor Name	Exposure (SS-KRD)			Factor Volatility	Return Impact Correlated	Marginal Contribution to TEV
	Portfolio	Benchmark	Net			
6M SS	0.14	0.13	0.01	39.1	-2.1	5.8
2Y SS	0.52	0.47	0.04	20.4	-2.1	3.0
5Y SS	0.84	0.75	0.09	9.6	-2.0	1.4
10Y SS	0.71	0.68	0.03	14.1	1.7	-1.8
20Y SS	0.34	0.33	0.01	17.0	2.2	-2.7
30Y SS	0.06	0.20	-0.15	20.1	2.4	-3.5

even further, increasing the mismatch our portfolio has in terms of duration, and so increasing its risk.¹² This result holds because we take into consideration the correlations between the different points in the Treasury curve. Without correlations, the analysis would be significantly less clear. The exhibit also reports the TEV elasticity of each of the risk factors, a concept introduced earlier. The interpretation is similar to the marginal contribution, but with normalized changes (percentage changes). This normalization makes the numbers more comparable across risk factors of very different nature. It is also useful when considering leveraging the entire portfolio proportionally. In our case, if we increase the exposure to the 10-year key rate point by 10%, from -0.36 to something around -0.40 (effectively reducing our long duration exposure), our TEV would be reduced by 4% (from 13.7 to 13.2 bps/month).

We now turn the analysis to the other component of the curve risk described above: the risk embedded into the portfolio exposure to the swap spread, that is, the spread between the swap and the Treasury curves. All securities that trade against the swap curve (e.g., all typical credit and securitized bonds) are exposed to this risk. Its analysis follows very closely that of the Treasury curve, so we only highlight the major risk characteristics of the portfolio along this dimension. Table 11 shows that in general our exposure to the swap spreads is smaller than the exposure to the Treasury curve. Remember that Treasuries do not load on this set of risk factors, so the market-weighted exposures are conse-

quently smaller. Looking at the profile of factor volatilities, one can see that its term structure of volatilities is U-shaped, with the short end extremely volatile and the five-year point having the lowest volatility. When comparing with the Treasury curve volatility profile (see Table 10), we can see significant differences, the aftermath of a strong liquidity crisis. Regarding net exposures, the exhibit shows that our largest mismatch is at the 30-year point, where we are short by 0.15 years. Interestingly, this is not the most expensive mismatch in terms of risk: When looking at the last column, we see that we would be able to change risk the most by manipulating the short end of our exposure to the swap spread curve, namely the six-month point.

The previous tables allow us to understand our exposures to the different types of curve risk and their impact both on the return and risk of our portfolios. They also guide us regarding what changes we can introduce to modify the risk profile of the portfolio. We now turn our attention to sources of risk that are more specific to particular asset classes. In particular, we start with the analysis of credit risk.

Credit Risk Instruments in the portfolio issued by corporations or entities that may default are said to have credit risk. The holders of these securities demand some extra yield—on top of the risk-free yield—to compensate for that risk. The extra yield is usually measured as a spread to a reference curve. For instance, for corporate bonds the reference curve is usually the swap curve. The level of credit spreads

determines to a large extent the credit risk exposure associated with the portfolio.¹³

There are several characteristics of credit bonds that are naturally associated with systematic sources of credit spread risk. For instance, depending on the business cycle, particular industries may be going through especially tough times. So industry membership is a natural systematic source of risk. Similarly, bonds with different credit ratings are usually treated as having different levels of credit risk. Credit rating could be another dimension we can use to measure systematic exposure to credit risk. Given these observations, it is common to see factor models for credit risk using industry and rating as the major systematic risk factors. Recent research suggests that risk models that directly use the spreads of the bonds instead of their ratings to assess risk perform

better for relatively short/medium horizons of analysis.¹⁴ Under this approach, the loading of a particular bond to a credit risk factor would be the commonly used spread duration multiplied by the bond's spread (the loading is termed $DTS = \text{Duration Times Spread} = OASD \times OAS$). By directly using the spread of the bond in the definition of the loading to the credit risk factors we do not need to assign specific risk factors to capture the rating or any similar quality-like effect. It will be automatically captured by the bond's loading to the credit risk factor and will adjust as the spread of the bond changes. We use different systematic risk factors only to distinguish among credit risk coming from different industries.¹⁵

The results of such an approach to the analysis of our portfolio are displayed in Table 12, which shows the typical industry risk factors

associated with credit risk. The portfolio has net positions in 27 industries, spanning all three major sectors: Industrials (IND), Utilities (UTI) and Financials (FIN). We saw before that we have a significant net exposure to financials in terms of market weights (12.2%, see Table 1). In terms of risk exposure, Table 12 shows that the net DTS exposure to the Banking industry is 0.32, clearly the highest across all sectors.¹⁶ However, the marginal contribution to TEV that comes from that industry, although high, is comparable to other industries, namely Brokerage, for which the net exposure is close to zero. This means that these two industries are close substitutes in terms of the current portfolio holdings. Actually, what is very interesting is the fact that the marginal contribution is negative for these industries, even though we are significantly overweighting them. The analysis suggests that if we increase our risk exposure to Banking, our risk would actually decrease. This result is again driven by the strong negative correlation between spreads in financials and the yield curve. Therefore, the exposure in banking is actually helping hedge out our (more risky) long duration position. This kind of analysis is only possible when you account for the correlations across factors. It is of course also dependent on the quality of the correlation estimations the model has.

Although the risk factors used to measure risk are predetermined in a linear factor model,

there is extreme flexibility in the way the risk numbers can be aggregated and reported.¹⁷ For example, as explained above, the risk model we use to generate the current risk reports does not use credit ratings as drivers of systematic credit risk. Instead, it relies on the DTS concept. However, once generated, the risk numbers can be reported using any portfolio partition. As an example, Table 13 shows the risk breakdown by rating. As reported in this table, the majority of risk is coming from our AAA exposure (10.9 bps/month), the bucket with the biggest mismatch in terms of net weight (-7.2%). This bucket includes Treasury and government-related securities, sectors that are underweighted in the portfolio leading to significant risk. This is even clearer when we look into the isolated TEV numbers. If we had mismatches only on AAAs, the risk of our portfolio would be 37.4 bps/month, instead of the actual 13.7: our other exposures (namely the one to single As) hedge the risk from AAAs. This table also reports the systematic betas associated with each of the rating subportfolios. These betas add up to the portfolio beta, when we use the portfolio weights (not NMW) as weights in the summation. Systematic betas of zero identify buckets for which the portfolio has (close to) no holdings. The table shows that a movement of 10 basis points in the benchmark leads to a 11.2 basis points return in the AAA subcomponent of the portfolio. The beta of 0.37

Table 14 MBS (spread) Prepayment Risk

Factor Name	Exposure (OASD)			Factor Volatility	Return Impact Correlated	Marginal Contribution to TEV
	Portfolio	Benchmark	Net			
MBS New Discount	0.00	0.00	0.00	36.8	-1.2	3.3
MBS New Current	0.00	0.04	-0.04	24.5	-0.3	0.6

MBS Seasoned Premium	0.65	0.46	0.19	29.8	0.1	-0.2
MBS Ginnie Mae 30Y	0.31	0.21	0.10	6.1	-0.1	0.0
MBS Fannie Mae 15Y	0.00	0.11	-0.11	15.7	0.4	-0.4
MBS Ginnie Mae 15Y	0.00	0.01	-0.01	12.3	0.5	-0.4

for the BAA3 component of the portfolio does not signal low volatility for this subportfolio. It indicates mainly low correlation with the benchmark. This is probably due to a larger component of idiosyncratic risk for this set of bonds.

Prepayment Risk Securitized products are generally exposed to prepayment risk. The most common of the securitized products are the residential MBS (RMBS or simply MBS). These securities represent pools of deals that allow the borrower to prepay their debt before the maturity of the loan/deal, typically when prevailing lending rates are lower. This option means an extra risk to the holder of the security, the risk of holding cash exactly when reinvestment rates are low. Therefore, these securities have two major sources of risk: interest rates (including convexity) and prepayment risk.

Some part of the prepayment risk can be expressed as a function of interest rates via a prepayment model. This risk will be captured as part of interest-rate risk using the key rate durations and the convexity. These securities usually have negative convexity because usually prepayments increase (decrease) with decreasing (increasing) interest rates, thereby reducing price appreciation (increase price depreciation). The remaining part of prepayment risk—that is not captured by the prepayment model—must be modeled with additional systematic risk factors. Typically, the volatility of prepayment speeds (and therefore of risk) on MBS securities depends on three characteristics:

program/term of the deal, if the bond is priced at discount or premium (e.g., if the coupon on the bond is bigger than the current mortgage rates) and how seasoned the bond is. This analysis suggests that the systematic risk factors in a risk model should span these three characteristics of the securities.

Table 14 shows a potential set of risk factors that capture the three characteristics discussed above. Programs identified as having different prepayment characteristics are the conventional (Fannie Mae) 30-year bonds (the base case used for the analysis), the 15-year conventional (Fannie Mae) bonds, as well as the Ginnie Mae 30- and 15-year bonds. The age of bonds is captured by factors distinguishing between new and aged deals. Finally, each bond is also classified by the price of the security—discount, current, or premium. In this example there are no seasoned discounted bonds, given the unprecedented level of mortgage rates as of June 2010. In terms of risk exposures, the exhibit shows that we are currently underweighting 15-year conventional bonds, and overweighting 30-year Ginnie Mae bonds.

Interaction between Sources of Risk So far we analyzed the major sources of spread risk: credit and prepayment. To do this, we conveniently used two asset classes—credit and agency RMBS, respectively—where one can argue that these sources of risk appear relatively isolated. However, recent developments have made very clear that these sources of risk appear simultaneously in other major asset

classes, including non-agency RMBS, home equity loans and CMBS.¹⁸ When designing a risk model for a particular asset class, one should be able to anticipate the nature of the risks the asset class exhibits currently or may encounter in the future. The design and ability to segregate between these two kinds of risk depends also on the richness of the bond indicatives and analytics available to the researcher. For this last point, it is imperative that the researcher understands well the pricing model and assumptions made to generate the analytics typically used as inputs in a risk model. This allows the user to fully understand the output of the model, as well as its applicability and shortcomings.

Other Sources of Risk There are other sources of systematic risk we did not detail in this section. They may be important sources of risk for particular portfolios. Specific risk models can be designed to address them. We now mention some of them briefly.

Implied Volatility Risk Many fixed income securities have embedded options (e.g., callable bonds). This means that the expected future volatility (implied volatility¹⁹) of the interest rate or other discount curves used to price the security plays a role in the value of that option. If expected volatility increases, options generally become more expensive, affecting the prices of bonds with embedded options. For example, callable bonds will become cheaper with increasing implied volatility since the bond holder is short optionality (the right of the issuer to call the bond). Therefore, the exposure of the portfolio to the implied volatility of the yield curve is also a source of risk that should be accounted for. The sensitivity of securities to changes of implied volatilities is measured by vega, which is calculated using the security pricing model. Implied volatility factors can be either calculated by the market prices of liquid fixed income options (caps, floors, and swaptions), or implied by the returns of bonds with embedded options within each asset class.

Liquidity Risk Many fixed income securities are traded over-the-counter, in decentralized markets. Some trade infrequently, making them illiquid. It is therefore hard to establish their fair price. These bonds are said to be exposed to liquidity risk. The holder of illiquid bonds would have to pay a higher price to liquidate its position, usually meaning selling at a discount. This discount is uncertain and varies across the business cycle. For instance, the discount can be significant in a liquidity crisis, such as the one we experienced in 2008. The uncertainty about this discount means that, everything equal, a more illiquid bond will be riskier. This extra risk can be captured through liquidity risk factors. For instance, in the Treasury markets, one generally refers to the difference in volatility between an on-the-run and an off-the-run Treasury bond as liquidity risk.

Inflation Risk Inflation-linked securities are priced based on the expectation of future inflation. Uncertainty about this variable adds to the volatility of the bond over and above the volatility from other sources of risk, such as the nominal interest rates. Expected inflation is not an observed variable in the marketplace but can be extracted from the prices on inflation-linked government bonds and inflation swaps. Expected inflation risk factors can be constructed by summarizing this information. The sensitivity of securities to expected inflation is calculated using a specialized pricing model and is usually called inflation duration.

Tax-Policy Risk Many municipal securities are currently tax-exempt. This results in added benefit to their holders. This benefit—incorporated in the price of the security—depends on the level of exemption allowed. Uncertainty around tax policy—tax-policy risk—adds to the risk of these securities. Once again, tax-policy risk factors cannot be observed in the marketplace and must be extracted from the prices of municipal securities. The return of municipal securities in excess of interest rates is driven

partially by tax-policy expectations changes. However, it is also driven by changes in the creditworthiness of the municipal issuers as well as other factors. In this case it is difficult to separate tax-policy risk factors from other factors driving municipal bond spreads. Therefore, instead of specific tax-policy factors we usually extract factors representing the overall spread risk of municipal securities. This exercise is performed in a similar way to the credit risk model, where securities are partitioned into groups of “similar” risk by geography, bond-type (general obligation versus revenue), tax-status, and the like.²⁰

Issue-Level Reports

The previous analysis focused on the systematic sources of risk. We now turn our attention to the idiosyncratic or security-specific risk embedded in our portfolio. This risk measures the volatility the portfolio has due to news or demand–supply imbalances specific to the individual issues/issuers it holds. Therefore, the idiosyncratic risk is independent across issuers and diversifies away as the number of issues in the portfolio increases: Negative news about some issuers is canceled by positive news about others. For relatively small portfolios, the idiosyncratic risk may be a substantial compo-

nent of the total risk. This can be seen in our example, as our portfolio has only 27 issuers. Table 6 shows that the idiosyncratic volatility of our portfolio is 11.1 bps/month, more than twice the idiosyncratic volatility of the benchmark (5.6 bps/month). When looking at the tracking error volatility net of benchmark, Table 6 shows that our specific risk is 10.1 bps/month and larger than the systematic component (9.3 bps/month). This means that, typically, a major component of the monthly net return is driven by events affecting only individual issues or issuers. Therefore, monitoring these individual exposures is of paramount importance.

The idiosyncratic risk of each bond is a function of two variables: its net market weight and its idiosyncratic volatility. This last parameter depends on the nature of the bond issuer. For instance, a bond from a distressed firm has much higher idiosyncratic volatility than one from a government-related agency.

Table 15 provides a summary of the idiosyncratic risk for the top 10 positions by market weight in our portfolio. Not surprisingly, our top seven holdings are Treasuries and MBS securities, in line with the constitution of the index we are using as benchmark. Moreover, these positions have significant market weights, given that our portfolio contains

Table 15 Issue Specific Risk

Identifier	Ticker	Description	Maturity	Spread (bps)	Market Weight (%)		Idiosyncratic TEV
					Portfolio	Net	
912828KF	US/T	US Treasury Notes	2/28/2014	4	5.4	5.2	0.4

20029PAG	CMCSA	Comcast Cable Communication	5/1/2017	222	2.2	2.2	2.4
59018YSU	BAC	Merrill Lynch & Co.	2/3/2014	300	2.1	2.1	2.9
912828KV	US/T	US Treasury Notes	5/31/2014	1	2.1	1.9	0.2

only 50 positions. Even though we see large concentrations, the idiosyncratic TEV for the top holdings is small, as they are not exposed to significant name risk. The last column of the table shows that from this group the largest idiosyncratic risk comes from two corporate bonds (issued by Comcast Cable Communication “CMCSA” and Merrill Lynch “BAC”). This is not surprising, as these are the type of securities with larger event risk. Even within corporates, idiosyncratic risk can be quite diverse. In particular, it usually depends on the industry, duration, and level of distress of the issuer (usually proxied by rating, but in our model by the spread of the bond). For instance, the net position for both the CMCSA and BAC bonds is similar (2.2% and 2.1% respectively), but even though the maturity of the BAC bond is significantly shorter, its spread is higher, delivering a higher idiosyncratic risk (2.9 versus 2.4 bps/month). The fact that BAC is a firm from an industry (Financials) that experienced significant volatility in the recent past also contributes to higher idiosyncratic volatility. To manage the idiosyncratic risk in the portfolio one should pay particular attention to mismatches between the portfolio and benchmark for bonds with large spreads or long durations. These would tend to affect disproportionately the idiosyncratic risk of the portfolio.

Although important, the information in Table 15 is not enough to fully assess the idiosyncratic risk embedded in the portfolio. For instance, one could buy credit protection to BAC through a credit default swap (CDS). In this case, our exposure to this issuer may not be significant, even though, taken separately, the position reported in this exhibit is relevant. More generally, idiosyncratic risk is independent across issuers, but what happens within a particular issuer? A good risk model should have the ability to account for the fact that the idiosyncratic risk of two securities from the same issuer is correlated, as they are both subject to the same company-specific events. This is especially the case for corporates and emerg-

ing market securities. Moreover, it is important to note that the correlation between issues from the same issuer is not constant either. For an issuer in financial distress, all claims to their assets (bonds, equities, convertibles, etc.) tend to move together, in the absence of specific circumstances. This means that the idiosyncratic correlation between issues from that issuer should be high. Therefore, adding more issues from that issuer to the portfolio does not deliver additional diversification. On the other end, securities from firms that enjoy very strong financial wealth can move quite differently, driven by liquidity or other factors. In this case, one can have some diversification of idiosyncratic risk (although limited) even when adding issues from that same issuer into the portfolio.

To help us understand the net effect of all these points, we need to know the issuers that contribute the most to idiosyncratic risk. When aggregating risk from the issue (as shown in Table 15) to the issuer level, the correlations referred to above should be fully taken into account. Table 16 shows the results of this exercise for the 10 issuers with the highest idiosyncratic TEV. Our riskiest exposure comes from Johnson & Johnson (JNJ), with 3.7 bps/month of issuer risk. We can also observe that idiosyncratic TEV is not monotonic in the NMW: We have JNJ and President & Fellows of Harvard “HARVRD” with the same NMW, but the former is significantly more risky (3.7 versus 2.0 bps/month). It is possible to have important issuer risk even for names we do not have in our portfolio, if they have significant market weight in the benchmark. Finally, note that because the idiosyncratic risk across issuers is independent, we can easily calculate the cumulative risk of several issuers. For example, the total idiosyncratic risk of the first two issuers is given by

$$TEV_{idio}^{JNJ+D} = \sqrt{3.7^2 + 2.8^2} = 4.6$$

Another important interpretation from Table 16 is that these are our biggest name exposures in our portfolio. In this case, we are overweight in all of them. Therefore, we should

Table 16 Issuer Specific Risk

Ticker	Name	Sector	NMW (%)	Idiosyncratic TEV
JNJ	Johnson & Johnson	Pharmaceuticals	2.0	3.7
D	Dominion Resources Inc	Electric	1.8	2.8
CMCSA	Comcast Cable Communication	Media_cable	2.0	2.1

C	Citigroup Inc	Banking	1.5	1.7
BAC	Merrill Lynch & Co.	Banking	1.6	1.6
RBS	Charter One Bank Fsb	Banking	1.6	1.4

not have negative views about any of them. If this is not the case, then we are assuming an unintended name risk. This risk should be promptly taken out of the portfolio, in favor of another issuer with similar characteristics and for which we do not have negative views about. This interactive exercise can easily be performed with a good and flexible optimizer.

Scenario Analysis Report

Scenario analysis is another useful way to gain additional perspective on the portfolio’s risk. There are many ways to perform this exercise. For instance, one may want to reprice the whole portfolio under a particular interest rate or spread scenario, and look at the hypothetical return under that scenario. Alternatively, one may look at the holdings of the portfolio

and see how they would have performed under particular stressed historical scenarios (e.g., the 1987 equity crash or the Asian crisis in 1997). One particular problem with this approach is the fact that, given the dynamic nature of the securities, the current portfolio did not exist with the current characteristics along all these historical episodes. A solution may be to try to price the current securities with the market variables at the time. Another solution is to represent the current portfolio as the set of loadings to all systematic risk factors in the factor risk model. We can then multiply these loadings by the historical realizations of the risk factors. The result is a set of historical systematic simulated returns. Figure 1 presents these returns for our portfolio over the last five years. As expected, the largest volatility came with the crisis of 2008, when the portfolio registered returns between –200

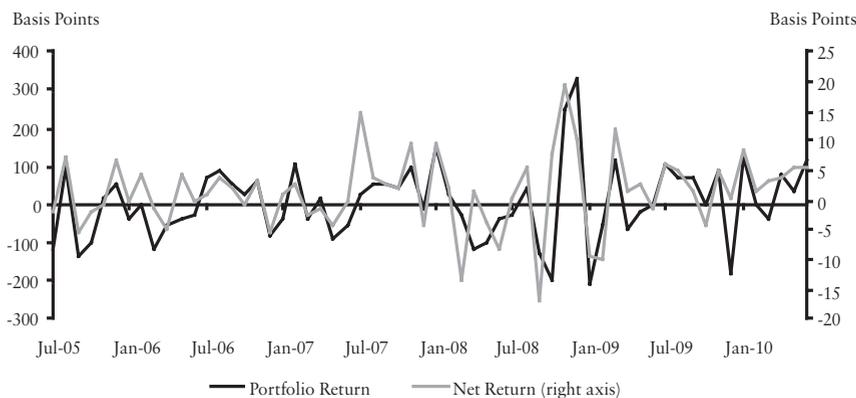

Figure 1 Historical Systematic Simulated Returns (basis points)

and +300 basis points. The largest underperformance against the benchmark appeared in September 2008, followed by the largest outperformance two months after, both at around 20 basis points.

This analysis has some limitations, especially for the portfolio under consideration, where idiosyncratic exposure is a major source of risk. This kind of risk is always very hard to pin down and obviously less relevant from an historical perspective, as the issuers in our current portfolio may have not witnessed any particular major idiosyncratic event in the past. However, these and other kinds of historical scenario analysis are very important, as they give us some indication of the magnitude of historical returns our portfolio might have encountered. They are usually the starting point for any stress testing. The researcher should always complement these with other nonhistorical scenarios relevant for the particular portfolio under analysis. One way to use the risk model to express such scenarios is discussed in the following section.

APPLICATIONS OF RISK MODELING

In this section, we illustrate several risk model applications typically employed for portfolio management. All applications make use of the fact that the risk model translates into a common, comparable set of numbers the imbalances the portfolio may have across many different dimensions. In some of the applications—*risk budgeting* and portfolio rebalancing—an optimizer that uses the risk model as an input is the optimal setting to perform the exercise.

Portfolio Construction and Risk Budgeting

Portfolio managers can be divided broadly into indexers (those that measure their returns rela-

tive to a benchmark index) and absolute return managers (typically hedge fund managers). In between stand the enhanced indexers we introduced previously in the entry. All are typically subject to a risk budget that prescribes how much risk they are allowed to take to achieve their objectives: Minimize transaction costs and match the index returns for the pure indexers, maximize the net return for the enhanced indexers, or maximize absolute returns for absolute return managers. In any of these cases, the manager has to merge all her views and constraints into a final portfolio. When constructing the portfolio, how can she manage the competing views, while respecting the risk budget? How can the views be combined to minimize the risk? What trade-offs can be made? Many different techniques can be used to structure portfolios in accordance with the manager's views. In particular, risk models are widely used to perform this exercise. They perform this task in a simple and objective manner: They can measure how risky each view is and how correlated they are. The manager can then compare the risk with the expected return of each of the views and decide on the optimal allocation across her views.

An example of a portfolio construction exercise using the risk model is the one we performed to construct the portfolio analyzed in the previous section.²¹ Figure 2 shows the exact problem we asked the optimizer to solve. We start the problem by defining an initial portfolio (empty in our case) and a tradable universe—the set of securities we allow the optimizer to buy or sell from. In our case, this is the Barclays US Aggregate index with issues having at least \$300 million of amount outstanding (in the Tradable Universe Options pane of the POINT[®] Optimizer window shown in Figure 2). The selection of this universe allows us to avoid having small issues in our portfolio, potentially increasing its liquidity. Pertaining to the risk model use (in the Objectives pane of the POINT[®] Optimizer window), the objective function used in the problem is to minimize Total TEV. This means that we are giving

Tradable Universe Options				
No.	Name	Type	Trade/Buy/Sell	Long/Short

Figure 2 Portfolio Construction Optimization Setup in the POINT® Optimizer

leeway to the risk model to choose a portfolio from the tradeable universe that minimizes the risk relative to the benchmark, in our case the Barclays US Aggregate index. In the Common Constraints pane, additional generic constraints have been imposed: a \$100 million final portfolio with a maximum number of 50 securities. In the Constraints on values aggregated by Buckets pane, we force the optimizer to tilt our portfolio to respect the portfolio manager’s views: long duration against the benchmark between 0.25 and 0.30 years and spreads between 100 and 150 bps higher than the benchmark. In the Constraints on each Issue/Issuer/Ticker pane, we impose a maximum under-/overweight of 2% per issuer, to ensure proper diversification.²² The characteristics of the portfolio resulting from this optimization problem were extensively analyzed in the previous section.

Portfolio Rebalancing

Managers need to rebalance their portfolios regularly. For instance, as time goes by, the characteristics of the portfolio may drift away from targeted levels. This may be due to the aging of its holdings, market moves, or issuer-specific events such as downgrades or defaults. The periodic re-alignment of a portfolio to its investment guidelines is called portfolio rebalancing. Similar needs arise in many different contexts: when managers receive extra cash to invest, get small changes to their mandates, want to tilt their views, and the like. Similar to portfolio construction, a risk model is very useful in the rebalancing exercise. During rebalancing, the portfolio manager typically seeks to sell bonds currently held and replace them with others having properties more consistent with the overall portfolio goals. Such buy and sell transactions are costly, and their cost must

Figure 3 Portfolio Rebalancing Optimization Setup in the POINT[®] Optimizer

be weighted against the benefit from moving the portfolio closer to its initial specifications. A risk model can tell the manager how much risk reduction (or increase) a particular set of transactions can achieve so that she can evaluate the risk adjustment benefits relative to the transaction cost.

As an example, suppose our portfolio manager wants to tone down the heavy overweight she has on banking. She wants to cap that overweight to 5% and wants to do it with no more than 10 trades. Finally, assume she wants no change to the market value of the final portfolio. We can use a setup similar to that of Figure 2, but adjusting some of the constraints. Figure 3 shows two of the constraints option panes in the POINT[®] Optimizer window, changed to allow for the new constraints. Specifically, in the first panel, we allow for 10 trades and, in the second, included an extra constraint for the banking industry.

Table 17 shows the trading list suggested by the POINT[®] Optimizer. Not surprisingly, the biggest sells are of financial companies. To replace them, the optimizer—using the risk model—recommends more holdings of Treasury and corporate bonds. (We need these last to keep the net yield of the portfolio high.) Remember that we concluded that our financial holdings were highly correlated with Treasuries, so the proposed swap is not surprising.

Interestingly, the extra constraint imposed on the optimization problem did not materially

change the risk of the portfolio. Results show that the risk actually decreased to around 13 bps/month. This is due to the extra three positions added to the portfolio that now has 53 securities. These extra securities allowed the portfolio to reduce both its systematic as well as its idiosyncratic risk.

Scenario Analysis

As described in the previous section, scenario analysis is a very popular tool both for risk management and portfolio construction. In this section, we illustrate another way to construct scenarios, this time using the covariance matrix of the risk model. In this context, users express views on the returns of particular financial variables, indexes, securities, or risk factors, and the scenario analysis tool (using the risk model) calculates their impact on the portfolio's (net) return.

Typically in this kind of scenario analysis, the views one has are only partial views. This means we can have specific views on how particular macro variables, asset classes, or risk factors will behave; but we hardly have views on all risk factors the portfolio under analysis is exposed to. This is when risk models may be useful. At the heart of the linear factor models described in this entry is a set of risk factors and the covariance matrix between them. They are being increasingly used in the context of scenario analysis as a way to “complete”

Table 17 Proposed Trading List

specific partial views or scenarios, delivering a full picture of the impact of the scenario in the return of the portfolio. Mechanically, what happens is the following: First, one translates the views into realizations of a subset of risk factors. Then the scenario is completed—using the risk model covariance matrix—to get the realizations of all risk factors. Finally, the portfolio's (net) loadings to all risk factors are used to get its (net) return under that scenario (by multiplying the loadings by the factor realizations under the scenario). This construction implies a set of assumptions that should be carefully understood. For instance, we assume that we can represent or translate our views as risk factor returns. So, if we have a view about the unemployment rate, and this is not a risk factor,²³ we cannot use this procedure to test our scenario. Also, to “complete” the scenario, we generally assume a stationary and normal multivariate distribution between all factors. These assumptions make this analysis less appropriate for looking at extreme events or regime shifts, for instance. But the analysis can be very useful in many circumstances.

As an example, consider using the scenario analysis to compute the model-implied empir-

ical durations (MED) of the portfolio we analyzed in detail previously in this entry. To do this, we express our views as changes in the curve factors. In our risk model, these are represented by the six key rate factors illustrated in Table 10. In particular, to calculate the model-implied empirical duration, we are going to assume that all six decrease by 25 bps/month, broadly in line with our managers' views.

Panel a of Table 18 shows that under this scenario, the portfolio returns 99 basis points, against the 93 of the benchmark. As expected given our longer duration, we outperform the benchmark. Due to the other exposures present in the portfolio and benchmark (e.g., spreads) and their average negative correlation with the curve factors, the duration implied by the scenario (MED) for our portfolio is only 3.96 (= 99/25) against the analytical 4.55. The scenario shows a similar decrease in the benchmark's duration.

Another characteristic imposed while constructing the portfolio was a targeted higher spread. As shown in Table 2, this resulted in an OAS for the portfolio of 157 bps against the 57 of the benchmark. It would be

Table 18 Spread Analysis

a. Analytical and Model-Implied Durations			
Universe	Return under Scenario (bp)	Durations	
		MED (scenario)	Analytical
Portfolio	99	3.96	4.55
Benchmark	93	3.72	4.30

b. Spread Contraction of 10%			
Universe		Restriction on YC movement	
		No Movement	Correlated
Portfolio		31	-3
Benchmark		32	0

interesting to evaluate the impact to the portfolio (net) return of a credit spread contraction of 10%. The portfolio is long spread duration (net OASD = 0.11, see Table 2), so we may expect our portfolio to outperform in this scenario. To do so, we analyze the results under two spread contraction scenarios: imposing no change in the yield curve (that is, an unchanged yield curve is part of the view) or allowing this change to be implied by the correlation matrix. (That is, the change in the yield curve is not part of the scenario. We have no views about it, but we allow it to change in a way historically consistent with our spread view.) Contrary to what one might expect, panel b of Table 18 shows that the effect in the net return is minimal under both scenarios. The higher spreads deliver no return advantage under this scenario. However, the absolute returns are quite different across the scenarios. When one allows the rates to move in a correlated fashion the net return drops close to zero: All positive return from the spread contraction is cancelled by the probable increase in the level of the curve and our long-duration exposure.

These very simple examples illustrate how one can look at reasonable scenarios to study the behavior of the portfolio or the benchmark under different environments. This scenario analysis does increase significantly the intuition the portfolio manager may have regarding the results from the risk model.

KEY POINTS

- Risk models describe the different imbalances of a portfolio using a common language. The imbalances are combined into a consistent and coherent analysis reported by the risk model.
- Risk models provide important insights regarding the different trade-offs existing in the portfolio. They provide guidance regarding how to balance them.
- Risk models in fixed income are unique in two different ways: First, the existence of good pricing models allows us to robustly calculate important analytics regarding the securities. These analytics can be used confidently as inputs into a risk model. Second, returns are not typically used directly to calibrate risk factors. Instead returns are first normalized into more invariant series (e.g., returns normalized by the duration of the bond).
- The fundamental systematic risk of all fixed income securities is interest rate and term structure risk. This is captured by factors representing risk-free rates and swap spreads of various maturities.
- Excess (of interest rates) systematic risk is captured by factors specific to each asset class. The most important components of such risk are credit risk and prepayment risk. Other risk factors that can be important are implied volatility, liquidity, inflation, and tax policy.

- Idiosyncratic risk is diversified away in large portfolios and indices but can become a very significant component of the total risk in small portfolios. The correlation of idiosyncratic risk of securities of the same issuer is nonzero and must be modeled very carefully.
- A good risk model provides detailed information about the exposures of a complex portfolio and can be a valuable tool for portfolio construction and management. It can help managers construct portfolios tracking a particular benchmark, express views subject to a given risk budget, and rebalance a portfolio while avoiding excessive transaction costs. Further, by identifying the exposures where the portfolio has the highest risk sensitivity it can help a portfolio manager reduce (or increase) risk in the most effective way.

NOTES

1. The Barclays Global Risk Model is available through POINT[®], Barclays portfolio management tool. It is a multi-currency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a *covariance matrix* of risk factors. The model has more than 700 factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.
2. Later in this entry, we refer to this risk number as Isolated TEV.
3. We arrive at this number by taking the square root of the sum of squares of all the numbers in the table: $10.9 = (8.5^2 + 1.7^2 + 3.0^2 + 5.1^2 + 3.0^2)^{0.5}$. Moreover, this number would represent the total systematic risk of the portfolio. This definition is developed later in the entry.
4. In this example, we focus only on the systematic component of risk. Later, the normalization is with respect to the total risk of the portfolio, including idiosyncratic risk.
5. For example, see Table 13 later in this entry.
6. Note that the contribution numbers are different from those from Table 5 because there we reported the contribution to systematic—not total—risk.
7. This result does not contradict the findings in Table 7, where we see that curve is the major source of risk. Remember that the curve risk can come from our corporate subportfolio.
8. Other curves that can be used are, for instance, the municipals (tax free) curve, derivatives-based curves, and the like.
9. This number is obtained by simply multiplying the net exposure by the factor volatility. The sign of the move depends on the interpretation of the factor. In the case of the yield curve movements we know that $R = -KRD \times \Delta KR$. In our example $-(-0.36) \times 44.2 = 15.9$.
10. This reversal is clearly related to the fact that the 10-year and the 20-year points in the curve are usually highly correlated. In our case, our short position on the 10-year point is more than compensated by the positive exposure in the 20-year. Netting out, the 20-year effect (long duration) dominates when all changes are taken in a correlated fashion.
11. The marginal contribution is the derivative of the TEV with respect to the loading of each factor, so its interpretation holds only locally. Therefore, a more realistic reading may be that if we reduce the exposure to the 10-year by 0.1 years, the TEV would be reduced by around 1.6 basis points.
12. This is a rationale very similar to the one used before, where we see all correlated impacts with the same sign.
13. Spreads are also compensation for sources of risk other than credit (e.g., liquidity), but

- for the sake of our argument, we treat them primarily as major indicators of credit risk.
14. For details, see Ben Dor et al. (2010).
 15. The general principle of a risk model is that the historical returns of assets contain information that can be used to estimate the future volatility of portfolio returns. However, good risk models must have the ability to interpret the historical asset returns in the context of the current environment. This translation is made when designing a particular risk model/factor and delivers risk factors that are as invariant as possible. This invariance makes the estimation of the factor distribution much more robust. In the particular case of the DTS, by including the spread in the loading (instead of using only the typical spread duration), we change the nature of the risk factor being estimated. The factor now represents percentage change in spreads, instead of absolute changes in spreads. The former has a significantly more invariant distribution. For more details, see Silva (2009a).
 16. The DTS units used in the report are based on an OASD stated in years and an OAS in percentage points. Therefore, a bond with an OASD = 5 and an OAS = 200 basis points would have a DTS of $5 \times 2 = 10$. The DTS industry exposures are the weighted sum of the DTS of each of the securities in that industry, the weights being the market weight of each security.
 17. For a detailed methodology on how to perform this customized analysis, Silva (2009b).
 18. For a further discussion, see Gabudean (2009).
 19. The volatility is called implied because it is calculated from the market prices of liquid options with the help of an option-pricing model.
 20. For more discussion, see Staal (2009).
 21. The example is constructed using the POINT[®] Optimizer. For more details, refer to Kumar (2010).
 22. Another way to ensure diversification would be to include the minimization of the idiosyncratic TEV as a specific goal in the objective function.
 23. Unemployment rate is not used as a factor in most short- and medium-term risk models.

Financial Econometrics

Scope and Methods of Financial Econometrics

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Financial econometrics is the econometrics of financial markets. It is a quest for models that describe financial time series such as prices, returns, interest rates, financial ratios, defaults, and so on. The economic equivalent of the laws of physics, econometrics represents the quantitative, mathematical laws of economics. The development of a quantitative, mathematical approach to economics started at the end of the 19th century in a period of great enthusiasm for the achievements of science and technology. Robert Engle and Clive Granger, two econometricians who shared the 2003 Nobel Prize in Economics Sciences, have contributed greatly to the field of financial econometrics.

Econometrics is the branch of economics that draws heavily on statistics for testing and analyzing economic relationships. Within econometrics, there are theoretical econometricians who analyze statistical properties of estimators of models. Several recipients of the Nobel Prize in Economic Sciences received the award as a result of their lifetime contribution to this branch of economics. To appreciate the importance of econometrics to the discipline of economics, when the first Nobel Prize in Economic Sciences was awarded in 1969, the co-recipients were two econometricians, Jan Tinbergen and Ragnar Frisch (who is credited with first us-

ing the term “econometrics” in the sense that it is known today). Further specialization within econometrics, and the subject of this entry, is financial econometrics.

As Jianqing Fan (2004) writes, financial econometrics uses statistical techniques and economic theory to address a variety of problems from finance. These include building financial models, estimation and inferences of financial models, volatility estimation, risk management, testing financial economics theory, capital asset pricing, derivative pricing, portfolio allocation, risk-adjusted returns, simulating financial systems, and hedging strategies, among others.

In this entry, we provide an overview of financial econometrics and the methods employed.

THE DATA GENERATING PROCESS

The basic principles for formulating quantitative laws in financial econometrics are the same as those that have characterized the development of quantitative science over the last four centuries. We write mathematical models, that is, relationships between different variables and/or variables in different moments and different places. The basic tenet of quantitative science is that there are relationships that do not change regardless of the moment or the place under consideration. For example, while sea waves might look like an almost random movement, in every moment and location the basic laws of hydrodynamics hold without change. Similarly, asset price behavior might appear to be random, but econometric laws should hold in every moment and for every set of assets.

There are similarities between financial econometric models and models of the physical sciences, but there are also important differences. The physical sciences aim at finding immutable laws of nature; econometric models model the economy or financial markets—artifacts subject to change. For example, financial markets in the form of stock exchanges have been in operation for two centuries. During this period, they have changed significantly both in the number of stocks listed and the type of trading. And the information available on transactions has also changed. Consider that in the 1950s, we had access only to daily closing prices and this typically the day after; now we have instantaneous information on every single transaction. Because the economy and financial markets are artifacts subject to change, econometric models are not unique representations valid throughout time; they must adapt to the changing environment.

While basic physical laws are expressed as differential equations, financial econometrics uses both continuous-time and discrete-time models. For example, continuous-time models are used in modeling derivatives where both the underlying and the derivative price are represented by stochastic (i.e., random) differential equations. In order to solve stochastic differential equations with computerized numerical methods, derivatives are replaced with finite differences. (Note that the stochastic nature of differential equations introduces fundamental mathematical complications. The definition of stochastic differential equations is a delicate mathematical process invented, independently, by the mathematicians Ito and Stratonovich. In the Ito-Stratonovich definition, the path of a stochastic differential equation is not the solution of a corresponding differential equation. However, the numerical solution procedure yields a discrete model that holds pathwise. See Focardi and Fabozzi [2004].) This process of discretization of time yields discrete time models. However, discrete time models used in financial econometrics are not necessarily the result of a process of discretization of continuous time models.

Let's focus on models in discrete time, the bread-and-butter of econometric models used in asset management. There are two types of discrete-time models: static and dynamic. *Static models* involve different variables at the same time. The well-known capital asset pricing model (CAPM), for example, is a static model. *Dynamic models* involve one or more variables at two or more moments. (This is true in discrete time. In continuous time, a dynamic model might involve variables and their derivatives at the same time.) Momentum models, for example, are dynamic models.

In a dynamic model, the mathematical relationship between variables at different times is called the *data generating process* (DGP). This terminology reflects the fact that, if we know the DGP of a process, we can simulate the process recursively, starting from initial conditions.

Consider the time series of a stock price p_t , that is, the series formed with the prices of that stock taken at fixed points in time, say daily. Let's now write a simple econometric model of the prices of a stock as follows:

$$p_{t+1} = \mu + \rho p_t + \varepsilon_{t+1} \quad (1)$$

This model tells us that if we consider any time $t+1$, the price of that stock at time $t+1$ is equal to a constant plus the price in the previous moment t multiplied by ρ plus a zero-mean random disturbance independent from the past, which always has the same statistical characteristics. If we want to apply this model to real-world price processes, the constants μ and ρ must be estimated. The parameter μ determines the trend and ρ defines the dependence between the prices. Typically ρ is less than but close to 1. A random disturbance of the type shown in the above equation is called a *white noise*.

If we know the initial price p_0 at time $t = 0$, using a computer program to generate random numbers, we can simulate a path of the price process with the following recursive equations:

$$\begin{aligned} p_1 &= \mu + \rho p_0 + \varepsilon_1 \\ p_2 &= \mu + \rho p_1 + \varepsilon_2 \end{aligned}$$

That is, we can compute the price at time $t = 1$ from the initial price p_0 and a computer-generated random number ε_1 and then use this new price to compute the price at time $t = 2$, and so on. The ε_i are independent and identically distributed random variables with zero mean. Typical choices for the distribution of ε are normal distribution, t -distribution, and stable non-Gaussian distribution. The distribution parameters are estimated from the sample.

It is clear that if we have a DGP we can generate any path. An econometric model that involves two or more different times can be regarded as a DGP. However, there is a more general way of looking at econometric models that encompasses both static and dynamic models. That is, we can look at econometric models from a perspective other than that of the

recursive generation of stochastic paths. In fact, we can rewrite our previous model as follows:

$$p_{t+1} - \mu - \rho p_t = \varepsilon_{t+1} \quad (2)$$

This formulation shows that, if we consider any two consecutive instants of time, there is a combination of prices that behave as random noise. More in general, an econometric model can be regarded as a mathematical device that reconstructs a noise sequence from empirical data.

This concept is visualized in Figure 1, which shows a time series of numbers p_t generated by a computer program according to the rule given by (2) with $\rho = 0.9$ and $\mu = 1$ and the corresponding time series ε_t . If we choose any pair of consecutive points in time, say $(t+1, t)$, the difference $p_{t+1} - \mu - \rho p_t$ is always equal to the series ε_{t+1} . For example, consider the points $p_{13} = 10.2918$, $p_{14} = 12.4065$. The difference $p_{14} - 0.9p_{13} - 1 = 2.1439$ has the same value as ε_{14} . If we move to a different pair we obtain the same result, that is, if we compute $p_{t+1} - 1 - 0.9p_t$, the result will always be the noise sequence ε_{t+1} .

To help intuition, imagine that our model is a test instrument: Probing our time series with our test instrument, we always obtain the same reading. Actually, what we obtain is not a constant reading but a random reading with mean zero and fixed statistical characteristics. The objective of financial econometrics is to find possibly simple expressions of different financial variables such as prices, returns, or financial ratios in different moments that always yield, as a result, a zero-mean random disturbance.

Static models (i.e., models that involve only one instant) are used to express relationships between different variables at any given time. Static models are used, for example, to determine exposure to different risk factors. However, because they involve only one instant, static models cannot be used to make forecasts; forecasting requires models that link variables in two or more instants in time.

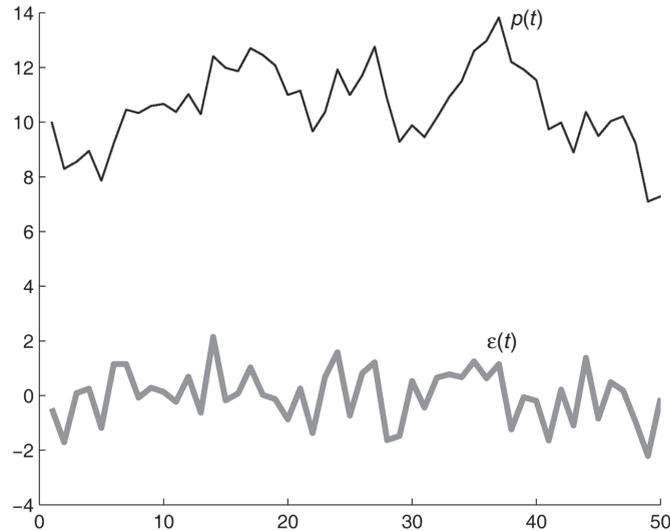

Figure 1 DGP and Noise Terms

FINANCIAL ECONOMETRICS AT WORK

Applying financial econometrics involves three key steps: (1) *model selection*, (2) *model estimation*, and (3) *model testing*.

In the first step, model selection, the modeler chooses (or might write *ex novo*) a family of models with given statistical properties. This entails the mathematical analysis of the model properties as well as economic theory to justify the model choice. It is in this step that the modeler decides to use, for example, regression on financial ratios or other variables to model returns.

In general, models include a number of free parameters that have to be estimated from sample data, the second step in applying financial econometrics. Suppose that we have decided to model returns with a regression model. This requires the estimation of the regression coefficients, performed using historical data. Estimation provides the link between reality and models. As econometric models are probabilistic models, any model can in principle describe our empirical data. We choose a family of models in the model selection phase and then de-

termine the optimal model in the estimation phase.

As mentioned, model selection and estimation are performed on historical data. As models are adapted (or fitted) to historical data there is always the risk that the fitting process captures ephemeral features of the data. Thus there is the need to test the models on data different from the data on which the models were estimated. This is the third step in applying financial econometrics, model testing. We assess the performance of models on fresh data.

We can take a different approach to model selection and estimation, namely statistical learning. *Statistical learning* combines the two steps—model selection and model estimation—insofar as it makes use of a class of universal models that can fit any data. Neural networks are an example of universal models. The critical step in the statistical learning approach is estimation. This calls for methods to restrict model complexity (i.e., the number of parameters used in a model).

Within this basic scheme for applying financial econometrics, we can now identify a number of modeling issues, such as:

- How do we apply statistics given that there is only one realization of financial series?
- Given a sample of historical data, how do we choose between linear and nonlinear models, or the different distributional assumptions or different levels of model complexity?
- Can we exploit more data using, for example, high-frequency data?
- How can we make our models more robust, reducing model risk?
- How do we measure not only model performance but also the ability to realize profits?

Implications of Empirical Series with Only One Realization

As mentioned, econometric models are *probabilistic models*: Variables are random variables characterized by a probability distribution. Generally speaking, probability concepts cannot be applied to single “individuals” (at least, not if we use a frequentist concept of probability). Probabilistic models describe “populations” formed by many individuals. However, empirical financial time series have only one realization. For example, there is only one historical series of prices for each stock—and we have only one price at each instant of time. This makes problematic the application of probability concepts. How, for example, can we meaningfully discuss the distribution of prices at a specific time given that there is only one price observation? Applying probability concepts to perform estimation and testing would require populations made up of multiple time series and samples made up of different time series that can be considered a random draw from some distribution.

As each financial time series is unique, the solution is to look at the single elements of the time series as the individuals of our population. For example, because there is only one realization of each stock’s price time series, we have to look at the price of each stock at different moments. However, the price of a stock (or of any other asset) at different moments is not a random in-

dependent sample. For example, it makes little sense to consider the distribution of the prices of a single stock in different moments because the level of prices typically changes over time. Our initial time series of financial quantities must be transformed; that is, a unique time series must be transformed into populations of individuals to which statistical methods can be applied. This holds not only for prices but for any other financial variable.

Econometrics includes transformations of the above type as well as tests to verify that the transformation has obtained the desired result. The DGP is the most important of these transformations. Recall that we can interpret a DGP as a method for transforming a time series into a sequence of noise terms. The DGP, as we have seen, constructs a sequence of random disturbances starting from the original series; it allows one to go backwards and infer the statistical properties of the series from the noise terms and the DGP. However, these properties cannot be tested independently.

The DGP is not the only transformation that allows statistical estimates. Differencing time series, for example, is a process that may transform *nonstationary time series* into *stationary time series*. A stationary time series has a constant mean that, under specific assumptions, can be estimated as an empirical average.

Determining the Model

As we have seen, econometric models are mathematical relationships between different variables at different times. An important question is whether these relationships are linear or nonlinear. Consider that every econometric model is an approximation. Thus the question is: Which approximation—linear or nonlinear—is better?

To answer this, it is generally necessary to consider jointly the linearity of models, the distributional assumptions, and the number of time lags to introduce. The simplest models are linear models with a small number of lags under

the assumption that variables are normal variables. A widely used example of normal linear models are regression models where returns are linearly regressed on lagged factors under the assumption that noise terms are normally distributed. A model of this type can be written as:

$$r_{t+1} = \beta f_t + \varepsilon_{t+1} \quad (3)$$

where r_t are the returns at time t and f_t are factors, that is, economic or financial variables. Given the linearity of the model, if factors and noise are jointly normally distributed, returns are also normally distributed.

However, the distribution of returns, at least at some time horizons, is not normal. If we postulate a nonlinear relationship between factors and returns, normally distributed factors yield a non-normal return distribution. However, we can maintain the linearity of the regression relationship but assume a non-normal distribution of noise terms and factors. Thus nonlinear models transform normally distributed noise into non-normal variables but it is not true that non-normal distributions of variables implies nonlinear models.

If we add lags (i.e., a time space backward), the above model becomes sensitive to the shape of the factor paths. For example, a regression model with two lags will behave differently if the factor is going up or down. Adding lags makes models more flexible but more brittle. In general, the optimal number of lags is dictated not only by the complexity of the patterns that we want to model but also by the number of points in our sample. If sample data are abundant, we can estimate a rich model.

Typically there is a trade-off between model flexibility and the size of the data sample. By adding time lags and nonlinearities, we make our models more flexible, but the demands in terms of estimation data are greater. An optimal compromise has to be made between the flexibility given by nonlinear models and/or multiple lags and the limitations due to the size of the data sample.

TIME HORIZON OF MODELS

There are trade-offs between model flexibility and precision that depend on the size of sample data. To expand our sample data, we would like to use data with small time spacing in order to multiply the number of available samples. *High-frequency data* or HFD (i.e., data on individual transactions) have the highest possible frequency (i.e., each individual transaction) and are irregularly spaced. To give an idea of the ratio in terms of numbers, consider that there are approximately 2,100 ticks per day for the median stock in the Russell 3000 (see Falkenberry, 2002). Thus the size of the HDF data set of one day for a typical stock in the Russell 3000 is 2,100 times larger than the size of closing data for the same day!

In order to exploit all available data, we would like to adopt models that work over time intervals of the order of minutes and, from these models, compute the behavior of financial quantities over longer periods. Given the number of available sample data at high frequency, we could write much more precise laws than those established using longer time intervals. Note that the need to compute solutions over forecasting horizons much longer than the time spacing is a general problem that applies at any time interval. For example, in asset allocation we need to understand the behavior of financial quantities over long time horizons. The question we need to ask is if models estimated using daily intervals can correctly capture the process dynamics over longer periods, such as years.

It is not necessarily true that models estimated on short time intervals, say minutes, offer better forecasts at longer time horizons than models estimated on longer time intervals, say days. This is because financial variables might have a complex short-term dynamics superimposed on a long-term dynamics. It might be that using high-frequency data, one captures the short-term dynamics without any improvement in the estimation of the long-term dynamics. That

is, with high-frequency data it might be that models get more complex (and thus more data-hungry) because they describe short-term behavior superimposed on long-term behavior. This possibility must be resolved for each class of models.

Another question is if it is possible to use the same model at different time horizons. To do so is to imply that the behavior of financial quantities is similar at different time horizons. This conjecture was first made by Benoit Mandelbrot (1963), who observed that long series of cotton prices were very similar at different time aggregations.

Model Risk and Model Robustness

Not only are econometric models probabilistic models, as we have already noted; they are only approximate models. That is, the probability distributions themselves are only approximate and uncertain. The theory of *model risk* and *model robustness* assumes that all parameters of a model are subject to uncertainty and attempts to determine the consequence of model uncertainty and strategies for mitigating errors.

The growing use of models in finance has heightened the attention to model risk and model-risk mitigation techniques. Asset management firms are beginning to address the need to implement methodologies that allow both robust estimation and robust optimization in the portfolio management process.

Performance Measurement of Models

It is not always easy to understand *ex ante* just how well (or how poorly) a forecasting model will perform. Because performance evaluations made on training data are not reliable, the evaluation of *model performance* requires separate data sets for training and for testing. Models are estimated on training data and tested on the test data. Poor performance might be due to

model misspecification, that is, models might not reflect the true DGP of the data (assuming one exists), or there might simply be no DGP.

Various measures of model performance have been proposed. For example, one can compute the correlation coefficient between the forecasted variables and their actual realizations. Each performance measure is a single number and therefore conveys only one aspect of the forecasting performance. Often it is crucial to understand if errors can become individually very large or if they might be correlated. Note that a simple measure of model performance does not ensure the profitability of strategies. This can be due to a number of reasons, including, for example, the risk inherent in apparently profitable forecasts, market impact, and transaction costs.

APPLICATIONS

There has been a greater use of econometric models in investment management since the turn of the century. Application areas include:

- Portfolio construction and optimization
- Risk management
- Asset and liability management

Each type of application requires different modeling approaches.

Portfolio Construction and Optimization

Portfolio construction and optimization require models to forecast returns: There is no way to escape the need to predict future returns. Passive strategies apparently eschew the need to forecast future returns of individual stocks by investing in broad indexes. They effectively shift the need to forecast to a higher level of analysis and to longer time horizons.

Until recently, the mainstream view was that financial econometric models could perform dynamic forecasts of volatility but not of

expected returns. However, volatility forecasts are rarely used in portfolio management. With the exception of some proprietary applications, the most sophisticated models used in portfolio construction until recently were factor models where forecasts are not dynamic but consist in estimating a drift (i.e., a constant trend) plus a variance-covariance matrix.

Since the late 1990s, the possibility of making dynamic forecasts of both volatility and expected returns has gained broad acceptance. During the same period, it became more widely recognized that returns are not normally distributed, evidence that had been reported by Mandelbrot (1963). Higher moments of distributions are therefore important in portfolio management and therefore require representation and estimation of nonnormal distributions.

As observed above, the ability to correctly forecast expected returns does not imply, per se, that there are profit opportunities. In fact, we have to take into consideration the interplay between expected returns, higher moments, and transaction costs. As dynamic forecasts typically involve higher portfolio turnover, transaction costs might wipe out profits. As a general comment, portfolio management based on dynamic forecasts calls for a more sophisticated framework for optimization and risk management with respect to portfolio management based on static forecasts.

Regression models appear to form the core of the modeling efforts to predict future returns at many asset management firms. Regression models regress returns on a number of predictors. Stated otherwise, future returns are a function of the value of present and past predictors. Predictors include financial ratios such as earning-to-price ratio or book-to-price ratio and other fundamental quantities; predictors might also include behavioral variables such as market sentiment. A typical formula of a regressive model is the following:

$$r_{i,t+1} = \alpha_i + \sum_{j=1} \beta_{ij} f_{j,t} + \varepsilon_{i,t+1} \quad (4)$$

where

$$r_{i,t+1} = \frac{P_{i,t+1} - P_{i,t}}{P_{i,t}}$$

is the return at time $t+1$ of the i -th asset, and the $f_{j,t}$ are factors observed at time t . While regressions are generally linear, nonlinear models are also used.

In general, the forecasting horizon in asset management varies from a few days for actively managed or hedge funds to several weeks for more traditionally managed funds. Dynamic models typically have a short forecasting horizon as they capture short-term dynamics. This contrasts with static models, such as the widely used multifactor models, which tend to capture long-term trends and ignore short-term dynamics.

The evolution of forecasting models over the last two decades has also changed the way forecasts are used. A basic utilization of forecasts is in stock picking/ranking systems, which have been widely implemented at asset management firms. The portfolio manager builds his or her portfolio combining the model ranking with the manager's personal views and within the constraints established by the firm. A drawback in using such an approach is the difficulty in properly considering the structure of correlations and the role of higher moments.

Alternatively, forecasts can be fed to an optimizer that automatically computes the portfolio weights. But because an optimizer implements an optimal trade-off between returns and some measure of risk, the forecasting model must produce not only returns forecasts but also measures of risk. If risk is measured by portfolio variance or standard deviation, the forecasting model must be able to provide an estimated variance-covariance matrix.

Estimating the variance-covariance matrix is the most delicate of the estimation tasks. Here is why. The number of entries of a variance-covariance matrix grows with the square of the number of stocks. As a consequence, the number of entries in a variance-covariance matrix

rapidly becomes very large. For example, the variance-covariance matrix of the stocks in the S&P 500 is a symmetric matrix that includes some 125,000 entries. If our universe were the Russell 5000, the variance-covariance matrix would include more than 12 million entries. The problem with estimating matrices of this size is that estimates are very noisy because the number of sample data is close to the number of parameters to estimate. For example, if we use three years of data for estimation, we have, on average, less than three data points per estimated entry in the case of the S&P 500; in the case of the Russell 5000, the number of data points would be one fourth of the number of entries to estimate! Robust estimation methods are called for.

Note that if we use forecasting models we typically have (1) an equilibrium variance-covariance matrix that represents the covariances of the long-run relationships between variables, plus (2) a short-term, time-dependent, variance-covariance matrix. If returns are not normally distributed, optimizers might require the matrix of higher moments.

A third utilization of forecasting models and optimizers is to construct model portfolios. In other words, the output of the optimizer is used to construct not an actual but a model portfolio. This model portfolio is used as input by portfolio managers.

Risk Management

Risk management has different meanings in different contexts. In particular, when optimization is used, risk management is intrinsic to the optimization process, itself a risk-return trade-off optimization. In this case, risk management is an integral part of the portfolio construction process.

However, in most cases, the process of constructing portfolios is entrusted to human portfolio managers who might use various inputs including, as noted above, ranking systems

or model portfolios. In these cases, portfolios might not be optimal from the point of view of risk management and it is therefore necessary to ensure independent risk oversight. This oversight might take various forms. One form is similar to the type of risk oversight adopted by banks. The objective is to assess potential deviations from expectations. In order to perform this task, the risk manager receives as input the composition of portfolios and makes return projections using static forecasting models.

Another form of risk oversight, perhaps the most diffused in portfolio management, assesses portfolio exposures to specific risk factors. As portfolio management is often performed relative to a benchmark and risk is defined as underperformance relative to the benchmark, it is important to understand the sensitivity of portfolios to different risk factors. This type of risk oversight does not entail the forecasting of returns. The risk manager uses various statistical techniques to estimate how portfolios move in function of different risk factors. In most cases, linear regressions are used. A typical model will have the following form:

$$r_{i,t} = \alpha_i + \sum_{j=1}^s \beta_{ij} f_{j,t} + \varepsilon_{i,t} \quad (5)$$

where

$$r_{i,t} = \frac{P_{i,t} - P_{i,t-1}}{P_{i,t-1}}$$

is the return observed at time t of the i -th asset, and the $f_{j,t}$ are factors observed at time t . Note that this model is fundamentally different from a regressive model with time lags as given by (4).

Asset-Liability Management

Asset-liability management (ALM) is typical of those asset management applications that require the optimization of portfolio returns at some fixed time horizon plus a stream of consumption throughout the entire life of the portfolio. ALM is important for managing portfolios

of institutional investors such as pension funds or foundations. It is also important for wealth management, where the objective is to cover the investor's financial needs over an extended period.

ALM requires forecasting models able to capture the asset behavior at short-, medium-, and long-term time horizons. Models of the long-term behavior of assets exist but are clearly difficult to test. Important questions related to these long-term forecasting models include:

- Do asset prices periodically revert to one or many common trends in the long run?
- Can we assume that the common trends (if they exist) are deterministic trends such as exponentials or are common trends stochastic (i.e., random) processes?
- Can we recognize regime shifts over long periods of time?

KEY POINTS

- Financial econometrics employs the same basic principles for formulating quantitative laws that characterized the development of quantitative science.
- Although there are similarities between financial econometric models and models of the physical sciences, important differences exist. For example, physical sciences seek immutable laws of nature, while econometric models model the economy or financial markets, which are artifacts subject to change.
- Econometric models are mathematical relationships between different variables at different times, and every econometric model is an approximation.
- Both continuous-time and discrete-time models are used in financial econometrics.
- Static models express relationships between different variables at any given time. Because

they involve only one instant in time, static models cannot be used to make forecasts since to do so models that link variables in two or more instants in time are required.

- Dynamic models involve one or more variables at two or more points in time; the data generating process in dynamic models is the mathematical relationship between variables at different times.
- Applying financial econometrics involves three key steps: (1) model selection, (2) model estimation, and (3) model testing.
- In model selection, the modeler selects the model based on an assessment of a model's properties and its fit to economic theory.
- Estimation provides the link between reality and models. In model estimation, the modeler applies financial econometric techniques to estimate the model's free parameters from sample data.
- The evaluation of model performance requires separate data sets for training and for testing because performance evaluations made on training data are not reliable.
- In investment management there has been increased use of econometric models in portfolio construction and optimization, risk management, and asset and liability management. A different modeling approach is needed for each type of application.

Regression Analysis: Theory and Estimation

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: The tools of financial econometrics play an important role in financial model building. The most basic tool in financial econometrics is regression analysis. The purpose in regression analysis is to estimate the relationship between a random variable and one or more independent variables. To understand and apply regression analysis one must understand the theory and the methodologies for estimating the parameters of the regression model. Moreover, when the assumptions underlying the model are violated, it is necessary to know how to remedy the problem.

Our first basic tool in econometrics is regression analysis. In regression analysis, we estimate the relationship between a random variable Y and one or more variables X_i . The variables X_i can be either deterministic variables or random variables. The variable Y is said to be the dependent variable because its value is assumed to be dependent on the value of the X_i 's. The X_i 's are referred to as the independent variables, regressor variables, or explanatory variables. Our primary focus is on the *linear regression* model. We will be more precise about what we mean by a "linear" regression model later in this entry. Let's begin with a discussion of the concept of dependence.

THE CONCEPT OF DEPENDENCE

Regressions are about *dependence* between variables. In this section we provide a brief discussion of how dependence is represented in both a deterministic setting and a probabilistic setting. In a deterministic setting, the concept of dependence is embodied in the mathematical notion of function. A function is a correspondence between the individuals of a given domain A and the individuals of a given range B . In particular, numerical functions establish a correspondence between numbers in a domain A and numbers in a range B .

In quantitative science, we work with variables obtained through a process of observation or measurement. For example, price is the observation of a transaction, time is the reading of a clock, position is determined with measurements of the coordinates, and so on. In quantitative science, we are interested in numerical functions $y = f(x_1, \dots, x_n)$ that link the results of measurements so that by measuring the independent variables (x_1, \dots, x_n) we can predict the value of the dependent variable y . Being the results of measurements, variables are themselves functions that link a set Ω of unobserved “states of the world” to observations. Different states of the world result in different values for the variables but the link among the variables remains constant. For example, a column of mercury in a thermometer is a physical object that can be in different “states.” If we measure the length and the temperature of the column (in steady conditions), we observe that the two measurements are linked by a well-defined (approximately linear) function. Thus, by measuring the length, we can predict the temperature.

In order to model uncertainty, we keep the logical structure of variables as real-valued functions defined on a set Ω of unknown states of the world. However, we add to the set Ω the structure of a probability space. A probability space is a triple formed by a set of individuals (the states of the world), a structure of events, and a probability function: $(\Omega, \mathfrak{S}, P)$. Random variables represent measurements as in the deterministic case, but with the addition of a probability structure that represents uncertainty. In financial econometrics, a “state of the world” should be intended as a complete history of the underlying economy, not as an instantaneous state.

Our objective is to represent dependence between random variables, as we did in the deterministic case, so that we can infer the value of one variable from the measurement of the other. In particular, we want to infer the future values of variables from present and past observations. The probabilistic structure offers different possibilities. For simplicity, let’s consider only two

variables X and Y ; our reasoning extends immediately to multiple variables. The first case of interest is the case when the dependent variable Y is a random variable while the independent variable X is deterministic. This situation is typical of an experimental setting where we can fix the conditions of the experiment while the outcome of the experiment is uncertain.

In this case, the dependent variable Y has to be thought of as a family of random variables Y_x , all defined on the same probability space $(\Omega, \mathfrak{S}, P)$, indexed with the independent variable x . Dependence means that the probability distribution of the dependent random variable depends on the value of the deterministic independent value. To represent this dependence we use the notation $F(y|x)$ to emphasize the fact that x enters as a parameter in the distribution. An obvious example is the dependence of a price random variable on a time variable in a stochastic price process.

In this setting, where the independent variable is deterministic, the distributions $F(y|x)$ can be arbitrarily defined. Important for the discussion of linear regressions in this entry is the case when the shape of the distribution $F(y|x)$ remains constant and only the mean of the distribution changes as a function of x .

Consider now the case where both X and Y are random variables. For example, Y might be the uncertain price of IBM stock tomorrow and X the uncertain level of the S&P 500 tomorrow. One way to express the link between these two variables is through their joint distribution $F(x,y)$ and, if it exists, their joint density $f(x,y)$. We define the joint and marginal distributions as follows:

$$\begin{aligned}
 F_{XY}(x, y) &= P(X \leq x, Y \leq y), \quad F_X(x) = P(X \leq x), \\
 & \quad F_Y(y) = P(Y \leq y) \\
 F_{XY}(x, y) &= \int_{-\infty}^x \int_{-\infty}^y f(x, y) dx dy \\
 F_X(x) &= \int_{-\infty}^x \int_{-\infty}^{-\infty} f(u, y) du dy = \int_{-\infty}^x \left(\int_{-\infty}^{-\infty} f(u, y) dy \right) du \\
 &= \int_{-\infty}^x f_X(u) du
 \end{aligned}$$

$$\begin{aligned}
 F_Y(x) &= \int_{-\infty}^{-\infty} \int_{-\infty}^y f(x, v) dx dv = \int_{-\infty}^y \left(\int_{-\infty}^{-\infty} f(x, v) dx \right) dv \\
 &= \int_{-\infty}^x f_Y(v) dv \\
 f(x|y) &= \frac{f(x, y)}{f_Y(y)}, f(y|x) = \frac{f(x, y)}{f_X(x)}
 \end{aligned}$$

We will also use the short notation:

$$\begin{aligned}
 f_X(x) &= f(x), f_Y(y) = f(y), f_{X|Y}(x|y) \\
 &= f(x|y), f_{Y|X}(y|x) = f(y|x)
 \end{aligned}$$

Given a joint density $f(x, y)$, we can also represent the functional link between the two variables as the dependence of the distribution of one variable on the value assumed by the other variable. In fact, we can write the joint density $f(x, y)$ as the product of two factors, the conditional density $f(y|x)$ and the marginal density $f_X(x)$:

$$f(x, y) = f(y|x)f_X(x) \quad (1)$$

This *factorization*—that is, expressing a joint density as a product of a marginal density and a conditional density—is the conceptual basis of financial econometrics. There are significant differences in cases where both variables X and Y are random variables, compared to the case where the variable X is deterministic. First, as both variables are uncertain, we cannot fix the value of one variable as if it were independent. We have to adopt a framework of conditioning where our knowledge of one variable influences our knowledge of the other variable.

The impossibility of making experiments is a major issue in econometrics. In the physical sciences, the ability to create the desired experimental setting allows the scientist to isolate the effects of single variables. The experimenter tries to create an environment where the effects of variables other than those under study are minimized. In economics, however, all the variables change together and cannot be controlled. Back in the 1950s, there were serious doubts that econometrics was possible. In fact, it was believed that estimation required the independence of samples while economic samples are never independent.

However, the framework of conditioning addresses this problem. After conditioning, the joint densities of a process are factorized into initial and conditional densities that behave as independent distributions. An econometric model is a probe that extracts independent samples—the noise terms—from highly dependent variables.

Let's briefly see, at the heuristic level, how conditioning works. Suppose we learn that the random variable X has the value x , that is, $X = x$. Recall that X is a random variable that is a real-valued function defined over the set Ω . If we know that $X = x$, we do not know the present state of the world but we do know that it must be in the subspace ($\omega \in \Omega: X(\omega) = x$). We call $(Y|X = x)$ the variable Y defined on this subspace. If we let x vary, we create a family of random variables defined on the family of subspaces ($\omega \in \Omega: X(\omega) = x$) and indexed by the value assumed by the variable X .

It can be demonstrated that the sets ($\omega \in \Omega: X(\omega) = x$) can be given a structure of probability space, that the variables $(Y|X = x)$ are indeed random variables on these probability spaces, and that they have (if they exist) the conditional densities:

$$f(y|x) = \frac{f(x, y)}{f_X(x)} \quad (2)$$

for $f_X(x) > 0$. In the discrete setting we can write

$$\begin{aligned}
 f(y|x) &= P(Y = y|X = x) \\
 f(x, y) &= P(X = x, Y = y)
 \end{aligned}$$

The conditional expectation $E[Y|X = x]$ is the expectation of the variable $(Y|X = x)$. Consider the previous example of the IBM stock price tomorrow and of the S&P 500 level tomorrow. Both variables have unconditional expectations. These are the expectations of IBM's stock tomorrow and of S&P 500's level tomorrow considering every possible state of the world. However, we might be interested in computing the expected value of IBM's stock price tomorrow if we know S&P 500's value tomorrow. This is the case if, for example, we are creating scenarios based on S&P 500's value.

If we know the level of the S&P 500, we do not know the present state of the world but we do know the subset of states of the world in which the present state of the world is. If we only know the value of the S&P 500, IBM's stock price is not known because it is different in each state that belongs to this restricted set. IBM's stock price is a random variable on this restricted space and we can compute its expected value.

If we consider a discrete setting, that is, if we consider only a discrete set of possible IBM stock prices and S&P 500 values, then the computation of the conditional expectation can be performed using the standard definition of conditional probability. In particular, the conditional expectation of a random variable Y given the event B is equal to the unconditional expectation of the variable Y set to zero outside of B and divided by the probability of B : $E[Y|B] = E[1_B Y]/P(B)$, where 1_B is the indicator function of the set B , equal to 1 for all elements of B , zero elsewhere. Thus, in this example,

$$\begin{aligned} E[\text{IBM stock price} \mid \text{S\&P 500 value} = s] \\ = E[1_{(\text{S\&P 500 value}=s)}(\text{IBM stock price})] / \\ P(\text{S\&P 500 value} = s) \end{aligned}$$

However, in a continuous-state setting there is a fundamental difficulty: The set of states of the world corresponding to any given value of the S&P 500 has probability zero; therefore we cannot normalize dividing by $P(B)$. As a consequence we cannot use the standard definition of conditional probability to compute directly the conditional expectation.

To overcome this difficulty, we define the conditional expectation indirectly, using only unconditional expectations. We define the conditional expectation of IBM's stock price given the S&P 500 level as that variable that has the same unconditional expectation as IBM's stock price on each set that can be identified by for the value of the S&P 500. This is a random variable which is uniquely defined for each state of the world up to a set of probability zero.

If the conditional density exists, conditional expectation is computed as follows:

$$E[Y|X = x] = \int_{-\infty}^{+\infty} yf(y|x)dy \quad (3)$$

We know from probability theory that the *law of iterated expectations* holds

$$E[E[Y|X = x]] = E[Y] \quad (4)$$

and that the following relationship also holds

$$E[XY] = E[XE[Y|X]] \quad (5)$$

Rigorously proving all these results requires a considerable body of mathematics and the rather difficult language and notation of σ -algebras. However, the key ideas should be sufficiently clear.

What is the bearing of the above on the discussion of regressions in this entry? Regressions have a twofold nature: They can be either (1) the representation of dependence in terms of conditional expectations and conditional distributions or (2) the representation of dependence of random variables on deterministic parameters. The above discussion clarifies the probabilistic meaning of both.

REGRESSIONS AND LINEAR MODELS

In this section we discuss regressions and, in particular, linear regressions.

Case Where All Regressors Are Random Variables

Let's start our discussion of regression with the case where all regressors are random variables. Given a set of random variables $\mathbf{X} = (Y, X_1, \dots, X_N)'$, with a joint probability density $f(y, x_1, \dots, x_N)$, consider the conditional expectation of Y given the other variables (X_1, \dots, X_N) :

$$Y = E[Y|X_1, \dots, X_N]$$

As we saw in the previous section, the conditional expectation is a random variable. We can therefore consider the residual:

$$\varepsilon = Y - E[Y|X_1, \dots, X_N]$$

The residual is another random variable defined over the set Ω . We can rewrite the above equation as a *regression equation*:

$$Y = E[Y|X_1, \dots, X_N] + \varepsilon \quad (6)$$

The deterministic function $y = \varphi(\mathbf{z})$ where

$$y = \varphi(\mathbf{z}) = E[Y|X_1 = z_1, \dots, X_N = z_N] \quad (7)$$

is called the *regression function*.

The following *properties of regression* equations hold.

Property 1. The conditional mean of the residual is zero: $E[\varepsilon|X_1, \dots, X_N] = 0$. In fact, taking conditional expectations on both sides of equation (7), we can write

$$E[Y|X_1, \dots, X_N] = E[E[Y|X_1, \dots, X_N] | X_1, \dots, X_N] + E[\varepsilon|X_1, \dots, X_N]$$

Because

$$E[E[Y|X_1, \dots, X_N]|X_1, \dots, X_N] = E[Y|X_1, \dots, X_N]$$

is a property that follows from the law of iterated expectations, we can conclude that $E[\varepsilon|X_1, \dots, X_N] = 0$.

Property 2. The unconditional mean of the residual is zero: $E[\varepsilon] = 0$. This property follows immediately from the multivariate formulation of the law of iterated expectations (4): $E[E[Y|X_1, \dots, X_N]] = E[Y]$. In fact, taking expectation of both sides of equation (7) we can write

$$E[Y] = E[E[Y|X_1, \dots, X_N]] + E[\varepsilon]$$

hence $E[\varepsilon] = 0$.

Property 3: The residuals are uncorrelated with the variables X_1, \dots, X_N : $E[\varepsilon X] = 0$. This follows from equation (6) by multiplying both sides of

equation (7) by X_1, \dots, X_N and taking expectations. Note however, that the residuals are not necessarily independent of the regressor X .

If the regression function is linear, we can write the following *linear regression equation*:

$$Y = a + \sum_{i=1}^N b_i X_i + \varepsilon \quad (8)$$

and the following linear regression function:

$$y = a + \sum_{i=1}^N b_i x_i \quad (9)$$

The rest of this entry deals with linear regressions. If the vector $\mathbf{Z} = (Y, X_1, \dots, X_N)'$ is jointly normally distributed, then the regression function is linear. To see this, partition \mathbf{z} , the vector of means $\boldsymbol{\mu}$, and the covariance matrix Σ conformably in the following way:

$$\mathbf{Z} = \begin{pmatrix} Y \\ \mathbf{X} \end{pmatrix}, \quad \mathbf{z} = \begin{pmatrix} y \\ \mathbf{x} \end{pmatrix}, \quad \boldsymbol{\mu} = \begin{pmatrix} \mu_y \\ \boldsymbol{\mu}_x \end{pmatrix},$$

$$\Sigma = \begin{pmatrix} \sigma_{yy} & \sigma_{xy} \\ \sigma_{yx} & \Sigma_{xx} \end{pmatrix}$$

where $\boldsymbol{\mu}$ is the vector of means and Σ is the covariance matrix. It can be demonstrated that the conditional density $(Y|\mathbf{X} = \mathbf{x})$ has the following expression:

$$(Y|\mathbf{X} = \mathbf{x}) \sim N(\alpha + \boldsymbol{\beta}'\mathbf{x}, \sigma^2) \quad (10)$$

where

$$\boldsymbol{\beta} = \Sigma_{xx}^{-1} \sigma_{xy}$$

$$\alpha = \mu_y - \boldsymbol{\beta}'\boldsymbol{\mu}_x \quad (11)$$

$$\sigma^2 = \sigma_{yy}^2 - \sigma_{yx} \Sigma_{xx}^{-1} \sigma_{xy}$$

The regression function can be written as follows:

$$y = \alpha + \boldsymbol{\beta}'\mathbf{x}, \text{ or explicitly: } y = \alpha + \sum_{i=1}^N \beta_i x_i \quad (12)$$

The normal distribution is not the only joint distribution that yields linear regressions. Spherical and elliptical distributions also yield linear regressions. Spherical distributions extend the multivariate normal distribution $N(0, \mathbf{I})$

(i.e., the joint distribution of independent normal variables). Spherical distributions are characterized by the property that their density is constant on a sphere, so that their joint density can be written as

$$f(x_1, \dots, x_N) = g(x_1^2 + \dots + x_N^2)$$

for some function g .

Spherical distributions have the property that their marginal distributions are uncorrelated but not independent, and can be viewed as multivariate normal random variables, with a random covariance matrix. An example of a spherical distribution used in financial econometrics is the multivariate t -distribution with m degrees of freedom, whose density has the following form:

$$f(x_1, \dots, x_N) = c \left[1 + \frac{1}{m}(x_1^2 + \dots + x_N^2) \right]^{-\frac{m+N}{2}}$$

The multivariate t -distribution is important in econometrics for several reasons. First, some sampling distributions are actually a t -distribution entries. Second, the t -distribution proved to be an adequate description of fat-tailed error terms in some econometrics models (although not as good as the stable Paretian distribution).

Elliptical distributions generalize the multivariate normal distribution $N(0, \Sigma)$. (See Bradley and Taqqu [2003].) Because they are constant on an ellipsoid, their joint density can be written as

$$f(\mathbf{x}) = g((\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma} (\mathbf{x} - \boldsymbol{\mu})), \mathbf{x}' = (x_1, \dots, x_N)$$

where $\boldsymbol{\mu}$ is a vector of constants and $\boldsymbol{\Sigma}$ is a strictly positive-definite matrix. Spherical distributions are a subset of elliptical distributions. Conditional distributions and linear combinations of elliptical distributions are also elliptical.

The fact that elliptical distributions yield linear regressions is closely related to the fact that the linear correlation coefficient is a meaningful measure of dependence only for elliptical distributions. There are distributions that do not factorize as linear regressions. The linear

correlation coefficient is not a meaningful measure of dependence for these distributions. The copula function of a given random vector $X = (X_1, \dots, X_N)'$ completely describes the dependence structure of the joint distribution of random variables $X_i, i = 1, \dots, N$. (See Embrechts, McNeil, and Straumann [2002].)

Linear Models and Linear Regressions

Let's now discuss the relationship between linear regressions and linear models. In applied work, we are given a set of multivariate data that we want to explain through a model of their dependence. Suppose we want to explain the data through a linear model of the type:

$$Y = \alpha + \sum_{i=1}^N \beta_i X_i + \varepsilon$$

We might know from theoretical reasoning that linear models are appropriate or we might want to try a linear approximation to nonlinear models. A linear model such as the above is not, per se, a linear regression unless we apply appropriate constraints. In fact, linear regressions must satisfy the three properties mentioned above. We call linear regressions linear models of the above type that satisfy the following set of assumptions such that

$$\alpha + \sum_{i=1}^N \beta_i X_i$$

is the conditional expectation of Y .

Assumption 1. The conditional mean of the residual is zero: $E[\varepsilon | X_1, \dots, X_N]$.

Assumption 2. The unconditional mean of the residual is zero: $E[\varepsilon] = 0$.

Assumption 3: The correlation between the residuals and the variables X_1, \dots, X_N is zero: $E[\varepsilon X] = 0$.

The above set of assumptions is not the full set of assumptions used when estimating a linear model as a regression but only consistency

conditions to interpret a linear model as a regression. We will introduce additional assumptions relative to how the model is sampled in the section on estimation. Note that the linear regression equation does not fully specify the joint conditional distribution of the dependent variables and the regressors. (This is a rather subtle point related to concept of exogeneity of variables. See Hendry [1995] for a further discussion.)

Case Where Regressors Are Deterministic Variables

In many applications of interest to the financial modeler, the regressors are deterministic variables. Conceptually, regressions with deterministic regressors are different from cases where regressors are random variables. In particular, as we have seen in a previous section, one cannot consider the regression as a conditional expectation. However, we can write a linear regression equation:

$$Y = \alpha + \sum_{i=1}^N \beta_i x_i + \varepsilon \quad (13)$$

and the following linear regression function:

$$y = \alpha + \sum_{i=1}^N \beta_i x_i \quad (14)$$

where the regressors are deterministic variables. As we will see in the following section, in both cases the least squares estimators are the same though the variances of the regression parameters as functions of the samples are different.

ESTIMATION OF LINEAR REGRESSIONS

In this section, we discuss how to estimate the linear regression parameters. We consider two main estimation techniques: maximum likelihood method and least squares method. A discussion of the sampling distributions of linear

regression parameters follow. The method of moments and the instrumental variables method are other methods that are used but are not discussed in this entry.

Maximum Likelihood Estimates

Let's reformulate the regression problem in a matrix form that is standard in regression analysis and that we will use in the following sections. Let's start with the case of a dependent variable Y and one independent regressor X . This case is referred to as the bivariate case or the simple linear regression. Suppose that we are empirically given T pairs of observations of the regressor and the independent variable. In financial econometrics these observations could represent, for example, the returns Y of a stock and the returns X of a factor taken at fixed intervals of time $t = 1, 2, \dots, T$. Using a notation that is standard in regression estimation, we place the given data in a vector \mathbf{Y} and a matrix \mathbf{X} :

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ \vdots \\ Y_T \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} 1 & X_1 \\ \vdots & \vdots \\ 1 & X_T \end{pmatrix} \quad (15)$$

The column of 1s represents constant terms. The regression equation can be written as a set of T samples from the same regression equation, one for each moment:

$$\begin{aligned} Y_1 &= \beta_0 + \beta_1 X_1 + \varepsilon_1 \\ &\vdots \\ Y_T &= \beta_0 + \beta_1 X_T + \varepsilon_T \end{aligned}$$

that we can rewrite in matrix form,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

where $\boldsymbol{\beta}$ is the vector of regression coefficients,

$$\boldsymbol{\beta} = \begin{pmatrix} \beta_0 \\ \beta_1 \end{pmatrix}$$

and $\boldsymbol{\varepsilon}$ are the residuals.

We now make a set of assumptions that are standard in regression analysis and that we will progressively relax. The assumptions for the linear regression model with normally

distributed residuals are:

1. The residuals are zero-mean, normally distributed independent variables $\varepsilon \sim N(0, \sigma_\varepsilon^2 \mathbf{I})$, where σ_ε^2 is the common variance of the residuals and \mathbf{I} is the identity matrix.
2. \mathbf{X} is distributed independently of the residuals ε .

(16)

The regression equation can then be written: $E(\mathbf{Y}|\mathbf{X}) = \mathbf{X}\beta$. The residuals form a sequence of independent variables. They can therefore be regarded as a strict white-noise sequence. As the residuals are independent draws from the same normal distribution, we can compute the log-likelihood function as follows:

$$\log L = -\frac{T}{2} \log(2\pi) - \frac{T}{2} \log(\sigma_\varepsilon^2) - \sum_{t=1}^T \left[\frac{(Y_t - \beta_0 - \beta_1 X_t)^2}{2\sigma_\varepsilon^2} \right] \quad (17)$$

The *maximum likelihood* (ML) principle requires maximization of the log-likelihood function. Maximizing the log-likelihood function entails first solving the equations:

$$\frac{\partial \log L}{\partial \beta_0} = 0, \quad \frac{\partial \log L}{\partial \beta_1} = 0, \quad \frac{\partial \log L}{\partial \sigma_\varepsilon^2} = 0$$

These equations can be explicitly written as follows:

$$\begin{aligned} \sum_{t=1}^T (Y_t - \beta_0 - \beta_1 X_t) &= 0 \\ \sum_{t=1}^T X_t (Y_t - \beta_0 - \beta_1 X_t) &= 0 \\ T\sigma_\varepsilon^2 - \sum_{t=1}^T [(Y_t - \beta_0 - \beta_1 X_t)^2] &= 0 \end{aligned}$$

A little algebra shows that solving the first two equations yields

$$\begin{aligned} \hat{\beta}_1 &= \frac{\overline{XY} - \overline{X}\overline{Y}}{\sigma_\varepsilon^2} \\ \hat{\beta}_0 &= (\overline{Y} - \beta_1 \overline{X}) \end{aligned} \quad (18)$$

where

$$\overline{X} = \frac{1}{T} \sum_{t=1}^T X_t, \quad \overline{XY} = \frac{1}{T} \sum_{t=1}^T X_t Y_t$$

and where $\bar{\sigma}_x, \bar{\sigma}_y$ are the empirical standard deviations of the sample variables X, Y respectively. Substituting these expressions in the third equation

$$\frac{\partial \log L}{\partial \sigma_\varepsilon^2} = 0$$

yields the variance of the residuals:

$$\hat{\sigma}_\varepsilon^2 = \frac{1}{T} \sum_{t=1}^T [(Y_t - \hat{\beta}_0 - \hat{\beta}_1 X_t)^2] \quad (19)$$

In the matrix notation established above, we can write the estimators as follows:

$$\text{For parameters: } \hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \quad (20)$$

For the variance of the regression:

$$\hat{\sigma}^2 = \frac{1}{T} (\mathbf{Y} - \mathbf{X}\hat{\beta})' (\mathbf{Y} - \mathbf{X}\hat{\beta}) \quad (21)$$

A comment is in order. We started with T pairs of given data $(X_i, Y_i), i = 1, \dots, T$ and then attempted to explain these data as a linear regression $Y = \beta_1 X + \beta_0 + \varepsilon$. We estimated the coefficients (β_1, β_2) with maximum likelihood estimation (MLE) methods. Given this estimate of the regression coefficients, the estimated variance of the residuals is given by equation (22). Note that equation (22) is the empirical variance of residuals computed using the estimated regression parameters. A large variance of the residuals indicates that the level of noise in the process (i.e., the size of the unexplained fluctuations of the process) is high.

Generalization to Multiple Independent Variables

The above discussion of the MLE method generalizes to multiple independent variables, N . We are empirically given a set of T observations

that we organize in matrix form,

$$\mathbf{Y} = \begin{pmatrix} Y_1 \\ \vdots \\ Y_T \end{pmatrix}, \mathbf{X} = \begin{pmatrix} X_{11} & \dots & X_{N1} \\ \vdots & \ddots & \vdots \\ X_{1T} & \dots & X_{NT} \end{pmatrix} \quad (22)$$

and the regression coefficients and error terms in the vectors,

$$\boldsymbol{\beta} = \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_N \end{pmatrix}, \boldsymbol{\varepsilon} = \begin{pmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_T \end{pmatrix} \quad (23)$$

The matrix \mathbf{X} which contains all the regressors is called the design matrix. The regressors \mathbf{X} can be deterministic, the important condition being that the residuals are independent. One of the columns can be formed by 1s to allow for a constant term (intercept). Our objective is to explain the data as a linear regression:

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

We make the same set of assumptions given by equation (17) as we made in the case of a single regressor. Using the above notation, the loglikelihood function will have the form

$$\log L = -\frac{T}{2} \log(2\pi) - \frac{T}{2} \log(\sigma_\varepsilon^2) - \frac{1}{2\sigma_\varepsilon^2} (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})' (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}) \quad (24)$$

The maximum likelihood conditions are written as

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = 0, \quad \frac{\partial \log L}{\partial \sigma_\varepsilon^2} = 0 \quad (25)$$

These equations are called normal equations. Solving the system of normal equations gives the same form for the estimators as in the univariate case:

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{Y} \\ \hat{\sigma}^2 = \frac{1}{T} (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}})' (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}) \quad (26)$$

The variance estimator is not unbiased. It can be demonstrated that to obtain an unbiased estimator we have to apply a correction that takes into account the number of variables by replac-

ing T with $T - N$, assuming $T > N$:

$$\hat{\sigma}^2 = \frac{1}{T - N} (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}})' (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}) \quad (27)$$

The MLE method requires that we know the functional form of the distribution. If the distribution is known but not normal, we can still apply the MLE method but the estimators will be different. We will not here discuss further MLE for nonnormal distributions.

Ordinary Least Squares Method

We now establish the relationship between the MLE principle and the *ordinary least squares* (OLS) method. OLS is a general method to approximate a relationship between two or more variables. We use the matrix notation defined above for MLE method; that is, we assume that observations are described by equation (23) while the regression coefficients and the residuals are described by equation (24).

If we use the OLS method, the assumptions of linear regressions can be weakened. In particular, we need not assume that the residuals are normally distributed but only assume that they are uncorrelated and have finite variance. The residuals can therefore be regarded as a white-noise sequence (and not a strict white-noise sequence as in the previous section). We summarize the linear regression assumptions as follows:

- Assumptions for the linear regression model:
1. The mean of the residuals is zero: $E(\boldsymbol{\varepsilon}) = 0$
 2. The residuals are mutually uncorrelated: $E(\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}') = \sigma^2\mathbf{I}$, where σ^2 is the variance of the residuals and \mathbf{I} is the identity matrix.
 3. \mathbf{X} is distributed independently of the residuals $\boldsymbol{\varepsilon}$.
- (28)

In the general case of a multivariate regression, the OLS method requires minimization of the sum of the squared residuals. Consider the

vector of residuals:

$$\boldsymbol{\varepsilon} = \begin{bmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_T \end{bmatrix}$$

The sum of the squared residuals ($SSR = (\varepsilon_1^2 + \dots + \varepsilon_T^2)$) can be written as $SSR = \boldsymbol{\varepsilon}'\boldsymbol{\varepsilon}$. As $\boldsymbol{\varepsilon} = \mathbf{Y} - \mathbf{X}\boldsymbol{\beta}$, we can also write

$$SSR = (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$$

The OLS method requires that we minimize the SSR. To do so, we equate to zero the first derivatives of the SSR:

$$\frac{\partial (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = 0$$

This is a system of N equations. Solving this system, we obtain the estimators:

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$$

These estimators are the same estimators obtained with the MLE method; they have an optimality property. In fact, the Gauss-Markov theorem states that the above OLS estimators are the best linear unbiased estimators (BLUE). "Best" means that no other linear unbiased estimator has a lower variance. It should be noted explicitly that OLS and MLE are conceptually different methodologies: MLE seeks the optimal parameters of the distribution of the error terms, while OLS seeks to minimize the variance of error terms. The fact that the two estimators coincide was an important discovery.

SAMPLING DISTRIBUTIONS OF REGRESSIONS

Estimated regression parameters depend on the sample. They are random variables whose distribution is to be determined. As we will see in this section, the sampling distributions differ depending on whether the regressors are

assumed to be fixed deterministic variables or random variables.

Let's first assume that the regressors are fixed deterministic variables. Thus only the error terms and the dependent variable change from sample to sample. The $\hat{\boldsymbol{\beta}}$ are unbiased estimators and $E[\hat{\boldsymbol{\beta}}] = \boldsymbol{\beta}$ therefore holds. It can also be demonstrated that the following expression for the variance of $\hat{\boldsymbol{\beta}}$ holds

$$E[(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})'] = \sigma^2(\mathbf{X}'\mathbf{X})^{-1} \quad (29)$$

where an estimate $\hat{\sigma}^2$ of σ^2 is given by (27).

Under the additional assumption that the residuals are normally distributed, it can be demonstrated that the regression coefficients are jointly normally distributed as follows:

$$\hat{\boldsymbol{\beta}} \sim N_N[\boldsymbol{\beta}, \sigma^2(\mathbf{X}'\mathbf{X})^{-1}] \quad (30)$$

These expressions are important because they allow us to compute confidence intervals for the regression parameters.

Let's now suppose that the regressors are random variables. Under the assumptions set forth in (29), it can be demonstrated that the variance of the estimators $\hat{\boldsymbol{\beta}}$ can be written as follows:

$$V(\hat{\boldsymbol{\beta}}) = E[(\mathbf{X}'\mathbf{X})^{-1}]V(\mathbf{X}'\boldsymbol{\varepsilon})E[(\mathbf{X}'\mathbf{X})^{-1}] \quad (31)$$

where the terms $E[(\mathbf{X}'\mathbf{X})^{-1}]$ and $V(\mathbf{X}'\boldsymbol{\varepsilon})$ are the empirical expectation of $(\mathbf{X}'\mathbf{X})^{-1}$ and the empirical variance of $(\mathbf{X}'\boldsymbol{\varepsilon})$, respectively.

The following terms are used to describe this estimator of the variance: *sandwich estimator*, *robust estimator*, and *White estimator*. The term *sandwich estimator* is due to the fact that the term $V(\mathbf{X}'\boldsymbol{\varepsilon})$ is sandwiched between the terms $E[(\mathbf{X}'\mathbf{X})^{-1}]$. These estimators are *robust* because they take into account not only the variability of the dependent variables but also that of the independent variables. Consider that if the regressors are a large sample, the sandwich and the classical estimators are close to each other.

DETERMINING THE EXPLANATORY POWER OF A REGRESSION

The above computations to estimate regression parameters were carried out under the assumption that the data were generated by a linear regression function with uncorrelated and normally distributed noise. In general, we do not know if this is indeed the case. Though we can always estimate a linear regression model on any data sample by applying the estimators discussed above, we must now ask the question: When is a linear regression applicable and how can one establish the goodness (i.e., explanatory power) of a linear regression?

Quite obviously, a linear regression model is applicable if the relationship between the variables is approximately linear. How can we check if this is indeed the case? What happens if we fit a linear model to variables that have non-linear relationships, or if distributions are not normal? A number of tests have been devised to help answer these questions.

Intuitively, a measure of the quality of approximation offered by a linear regression is given by the variance of the residuals. Squared residuals are used because a property of the estimated relationship is that the sum of the residuals is zero. If residuals are large, the regression model has little explanatory power. However, the size of the average residual in itself is meaningless as it has to be compared with the range of the variables. For example, if we regress stock prices over a broad-based stock index, other things being equal, the residuals will be numerically different if the price is in the range of dollars or in the range of hundreds of dollars.

Coefficient of Determination

A widely used measure of the quality and usefulness of a regression model is given by the *coefficient of determination* denoted by R^2 or R -squared. The idea behind R^2 is the following.

The dependent variable Y has a total variation given by the following expression:

$$\text{Total variation} = S_Y^2 = \frac{1}{T-1} \sum_{t=1}^T (Y_t - \bar{Y})^2 \quad (32)$$

where

$$\bar{Y} = \frac{1}{T-1} \sum_{t=1}^T Y_t$$

This total variation is the sum of the variation of the variable Y due to the variation of the regressors plus the variation of residuals $S_Y^2 = S_R^2 + S_\varepsilon^2$. We can therefore define the coefficient of determination:

$$\begin{aligned} \text{Coefficient of determination} = R^2 &= \frac{S_R^2}{S_Y^2} \\ 1 - R^2 &= \frac{S_\varepsilon^2}{S_Y^2} \end{aligned} \quad (33)$$

as the portion of the total fluctuation of the dependent variable, Y , explained by the regression relation. R^2 is a number between 0 and 1: $R^2 = 0$ means that the regression has no explanatory power, $R^2 = 1$ means that the regression has perfect explanatory power. The quantity R^2 is computed by software packages that perform linear regressions.

It can be demonstrated that the coefficient of determination R^2 is distributed as the well-known Student F distribution. This fact allows one to determine intervals of confidence around a measure of the significance of a regression.

Adjusted R^2

The quantity R^2 as a measure of the usefulness of a regression model suffers from the problem that a regression might fit data very well in-sample but have no explanatory power out-of-sample. This occurs if the number of regressors is too high. Therefore an adjusted R^2 is sometimes used. The adjusted R^2 is defined as R^2 corrected by a penalty function that takes into account the number p of regressors in the

model:

$$\text{Adjusted } R^2 = \frac{T-1}{T-N-1} \frac{S_R^2}{S_Y^2} \quad (34)$$

Relation of R^2 to Correlation Coefficient

The R^2 is the squared *correlation coefficient*. The correlation coefficient is a number between -1 and $+1$ that measures the strength of the dependence between two variables. If a linear relationship is assumed, the correlation coefficient has the usual product-moment expression:

$$r = \sqrt{\frac{\overline{XY} - \bar{X}\bar{Y}}{S_y X_x}} \quad (35)$$

USING REGRESSION ANALYSIS IN FINANCE

This section provides several illustrations of regression analysis in finance as well as the data for each illustration. However, in order to present the data, we limit our sample size.

Characteristic Line for Common Stocks

The *characteristic line* of a security is the regression of the excess returns of that security on the market excess returns:

$$r_i = \alpha_i + \beta_i r_M$$

where

r_i = the security excess return of a security over the risk-free rate

r_M = the market excess return of the market over the risk-free rate

We computed the characteristic lines of two common stocks, Oracle and General Motors (GM), and a randomly created portfolio consisting of 20 stocks equally weighted. We used the S&P 500 Index as a proxy for the market returns and the 90-day Treasury rate as a proxy for the risk-free rate. The return and excess return data are shown in Table 1. Note that there are 60 monthly observations used to estimate the characteristic line from December 2000 to November 2005. The 20 stocks comprising the portfolio are shown at the bottom of Table 1.

^aPortfolio includes the following 20 stocks: Honeywell, Alcoa, Campbell Soup, Boeing, General Dynamics, Oracle, Sun, General Motors, Procter & Gamble, Wal-Mart, Exxon, ITT, Unilever, Hilton, Martin Marietta, Coca-Cola, Northrop Grumman, Mercury Interact, Amazon, and United Technologies.

The estimated parameters for the two stocks and the portfolios are reported in Table 2. As can be seen from the table, the intercept term is not statistically significant; however, the slope, referred to as the beta of the characteristic line, is statistically significant. Typically for individual stocks, the R^2 ranges from 0.15 to 0.65. For Oracle and GM the R^2 is 0.23 and 0.26, respectively.

In contrast, for a randomly created portfolio, the R^2 is considerably higher. For our 20-stock portfolio, the R^2 is 0.79.

Note that some researchers estimate a stock's beta by using returns rather than excess returns. The regression estimated is referred to as the single-index market model. This model was first suggested by Markowitz as a proxy

Table 2 Characteristic Line of the Common Stock of General Motors, Oracle, and Portfolio: 12/1/2000–11/1/2005

Coefficient	Coefficient Estimate	Standard Error	<i>t</i> -statistic	<i>p</i> -value
GM				
α	-0.005	0.015	-0.348	0.729
β	1.406	0.339	4.142	0.000
R^2	0.228			
<i>p</i> -value	0.000			
Oracle				
α	-0.009	0.011	-0.812	0.420
β	1.157	0.257	4.501	0.000
R^2	0.259			
<i>p</i> -value	0.000			
Portfolio				
α	0.003	0.003	1.027	0.309
β	1.026	0.070	14.711	0.000
R^2	0.787			
<i>p</i> -value	0.000			

measure of the covariance of a stock with an index so that the full mean-variance analysis need not be performed. While the approach was mentioned by Markowitz (1959) in a footnote in his book, it was Sharpe (1963) who investigated this further. It turns out that the beta estimated using both the characteristic line and the single-index market model do not differ materially. For example, for our 20-stock portfolio, the betas differed only because of rounding off.

Empirical Duration of Common Stock

A commonly used measure of the interest-rate sensitivity of an asset's value is its duration. Duration is interpreted as the approximate percentage change in the value of an asset for a 100-basis-point change in interest. Duration can be estimated by using a valuation model or empirically by estimating from historical returns the sensitivity of the asset's value to changes in interest rates. When duration is measured in the latter way, it is called empirical duration. Since it is estimated using regression analysis, it is sometimes referred to as regression-based duration.

A simple linear regression for computing empirical duration using monthly historical data (see Reilly, Wright, and Johnson, 2007) is

$$y_{it} = \alpha_i + \beta_i x_t + e_{it}$$

where

y_{it} = the percentage change in the value of asset i for month t

x_t = the change in the Treasury yield for month t

The estimated β_i is the empirical duration for asset i .

We will apply this linear regression to monthly data from October 1989 to October 2003 shown in Table 3¹ for the following asset indexes:

- Electric Utility sector of the S&P 500
- Commercial Bank sector of the S&P 500
- Lehman U.S. Aggregate Bond Index (now the Barclays Capital U.S. Aggregate Bond Index)

The yield change (x_t) is measured by the Lehman Treasury Index. The regression results are shown in Table 4. We report the empirical duration (β_i), the t -statistic, the p -value, the R^2 , and the intercept term. Negative values are reported for the empirical duration. In practice, however, the duration is quoted as a positive value. For the Electric Utility sector and the Lehman U.S. Aggregate Bond Index, the empirical duration is statistically significant at any reasonable level of significance.

A multiple regression model to estimate the empirical duration that has been suggested is

$$y_{it} = \alpha_i + \beta_{1i} x_{1t} + \beta_{2i} x_{2t} + e_{it}$$

where y_{it} and x_{1t} are the same as for the simple linear regression and x_{2t} is the return on the S&P 500. The results for this model are also shown in Table 4.

The results of the multiple regression indicate that the returns for the Electric Utility sector are affected by both the change in Treasury rates and the return on the stock market as proxied

by the S&P 500. For the Commercial Bank sector, the coefficient of the changes in Treasury rates is not statistically significant, however the coefficient of the return on the S&P 500 is statistically significant. The opposite is the case for the Lehman U.S. Aggregate Bond Index. It is interesting to note that the duration for the Lehman U.S. Aggregate Bond Index as reported by Lehman Brothers was about 4.55 in November 2003. The empirical duration is 4.1. While the sign of the coefficient that is an estimate of duration is negative (which means the price moves in the opposite direction to the change in interest rates), market participants talk in terms of the positive value of duration for a bond that has this characteristic.

Predicting the 10-Year Treasury Yield²

The U.S. Department of the Treasury issues two types of securities: zero-coupon securities and

coupon securities. Securities issued with one year or less to maturity are called Treasury bills; they are issued as zero-coupon instruments. Treasury securities with more than one year to maturity are issued as coupon-bearing securities. Treasury securities from more than one year up to 10 years of maturity are called Treasury notes; Treasury securities with a maturity in excess of 10 years are called Treasury bonds. The U.S. Treasury auctions securities of specified maturities on a regular calendar basis. The Treasury currently issues 30-year Treasury bonds but had stopped issuance of them from October 2001 to January 2006.

An important Treasury coupon bond is the 10-year Treasury note. In this illustration we will try to forecast this rate based on two independent variables suggested by economic theory. A well-known theory of interest rates is that the interest rate in any economy consists of two components. This relationship is known as Fisher's law. The first is the expected

rate of inflation. The second is the real rate of interest. We use regression analysis to produce a model to forecast the yield on the 10-year Treasury note (simply, the 10-year Treasury yield)—the dependent variable—and the expected rate of inflation (simply, expected inflation) and the real rate of interest (simply, real rate).

The 10-year Treasury yield is observable, but we need a proxy for the two independent variables (i.e., the expected rate of inflation and the real rate of interest at the time) as they are not observable at the time of the forecast. Keep in mind that since we are forecasting, we do not use as our independent variable information that is unavailable at the time of the forecast. Consequently, we need a proxy available at the time of the forecast.

The inflation rate is available from the U.S. Department of Commerce. However, we need a proxy for expected inflation. We can use some type of average of past inflation as a proxy. In our model, we use a 5-year moving average. There are more sophisticated methodologies for calculating expected inflation, but the 5-year moving average is sufficient for our illustration. For example, one can use an exponential smoothing of actual inflation, a methodology used by the OECD. For the real rate, we use the rate on 3-month certificates of deposit (CDs). Again, we use a 5-year moving average.

The monthly data for the three variables from November 1965 to December 2005 (482 observations) are provided in Table 5. The regression results are reported in Table 6. As can be seen, the coefficients of both independent variables

are positive (as would be predicted by economic theory) and highly significant.

NONNORMALITY AND AUTOCORRELATION OF THE RESIDUALS

In the above discussion we assumed that there is no correlation between the residual terms. Let's now relax these assumptions. The correlation of the residuals is critical from the point of view of estimation. *Autocorrelation* of residuals is quite common in financial estimation where we regress quantities that are time series.

A time series is said to be autocorrelated if each term is correlated with its predecessor so that the variance of each term is partially explained by regressing each term on its predecessor.

Recall from the previous section that we organized regressor data in a matrix called the design matrix. Suppose that both regressors and the variable Y are time series data, that is, every row of the design matrix corresponds to a moment in time. The regression equation is written as follows:

$$Y = X\beta + \varepsilon$$

Suppose that residuals are correlated. This means that in general $E[\varepsilon_i \varepsilon_j] = \sigma_{ij} \neq 0$. Thus the variance-covariance matrix of the residuals $\{\sigma_{ij}\}$ will not be a diagonal matrix as in the case of uncorrelated residuals, but will exhibit nonzero off-diagonal terms. We assume that we can write

$$\{\sigma_{ij}\} = \sigma^2 \Omega$$

where Ω is a positive definite symmetric matrix and σ is a parameter to be estimated.

If residuals are correlated, the regression parameters can still be estimated without biases using the formula given by (26). However, this estimate will not be optimal in the sense that there are other estimators with lower variance of the sampling distribution. An optimal linear

unbiased estimator has been derived. It is called Aitken's *generalized least squares* (GLS) estimator and is given by

$$\hat{\beta} = (X' \Omega^{-1} X)^{-1} X' \Omega^{-1} Y \quad (36)$$

where Ω is the residual correlation matrix.

The GLS estimators vary with the sampling distribution. It can also be demonstrated that the variance of the GLS estimator is also given by the following "sandwich" formula:

$$V(\hat{\beta}) = E((\beta - \hat{\beta})(\beta - \hat{\beta})') = \sigma^2 (X' \Omega^{-1} X)^{-1} \quad (37)$$

This expression is similar to equation (28) with the exception of the sandwiched term Ω^{-1} . Unfortunately, (37) cannot be estimated without first knowing the regression coefficients. For this reason, in the presence of correlation of residuals, it is common practice to replace static regression models with models that explicitly capture autocorrelations and produce uncorrelated residuals.

The key idea here is that autocorrelated residuals signal that the modeling exercise has not been completed. If residuals are autocorrelated, this signifies that the residuals at a generic time t can be predicted from residuals at an earlier time. For example, suppose that we are linearly regressing a time series of returns r_t on N factors:

$$r_t = \alpha_1 f_{1,t-1} + \cdots + \alpha_N f_{N,t-1} + \varepsilon_t$$

Suppose that the residual terms ε_t are autocorrelated and that we can write regressions of the type

$$\varepsilon_t = \varphi \varepsilon_{t-1} + \eta_t$$

where η_t are now uncorrelated variables. If we ignore this autocorrelation, valuable forecasting information is lost. Our initial model has to be replaced with the following model:

$$r_t = \alpha_1 f_{1,t-1} + \cdots + \alpha_N f_{N,t-1} + \varepsilon_t$$

$$\varepsilon_t = \varphi \varepsilon_{t-1} + \eta_t$$

with the initial conditions ε_0 .

Detecting Autocorrelation

How do we detect the autocorrelation of residuals? Suppose that we believe that there is a reasonable linear relationship between two variables, for instance stock returns and some fundamental variable. We then perform a linear regression between the two variables and estimate regression parameters using the OLS method. After estimating the regression parameters, we can compute the sequence of residuals. At this point, we can apply tests such as the Durbin-Watson test or the Dickey-Fuller test to gauge the autocorrelation of residuals. If residuals are auto-correlated, we should modify the model.

PITFALLS OF REGRESSIONS

It is important to understand when regressions are correctly applicable and when they are not. In addition to the autocorrelation of residuals, there are other situations where it would be inappropriate to use regressions. In particular, we analyze the following cases, which represent possible pitfalls of regressions:

- Spurious regressions with integrated variables
- Collinearity
- Increasing the number of regressors

Spurious Regressions

The phenomenon of spurious regressions, observed by Yule in 1927, led to the study of cointegration. We encounter spurious regressions when we perform an apparently meaningful regression between variables that are independent. A typical case is a regression between two independent random walks. Regressing two independent random walks, one might find very high values of R^2 even if the two processes are independent. More in general, one might find high values of R^2 in the regression of two or more integrated variables, even if residuals are highly correlated.

Testing for regressions implies testing for cointegration. Anticipating what will be discussed there, it is always meaningful to perform regressions between stationary variables. When variables are integrated, regressions are possible only if variables are cointegrated. This means that residuals are a stationary (though possibly autocorrelated) process. As a rule of thumb, Granger and Newbold (1974) observe that if the R^2 is greater than the Durbin-Watson statistics, it is appropriate to investigate if correlations are spurious.

Collinearity

Collinearity, also referred to as multicollinearity, occurs when two or more regressors have a linear deterministic relationship. For example, there is collinearity if the design matrix

$$\mathbf{X} = \begin{pmatrix} X_{11} & \cdots & X_{N1} \\ \vdots & \ddots & \vdots \\ X_{1T} & \cdots & X_{NT} \end{pmatrix}$$

exhibits two or more columns that are perfectly proportional. Collinearity is essentially a numerical problem. Intuitively, it is clear that it creates indeterminacy as we are regressing twice on the same variable. In particular, the standard estimators given by (26) and (27) cannot be used because the relative formulas become meaningless.

In principle, collinearity can be easily resolved by eliminating one or more regressors. The problem with collinearity is that some variables might be very close to collinearity, thus leading to numerical problems and indeterminacy of results. In practice, this might happen for many different numerical artifacts. Detecting and analyzing collinearity is a rather delicate problem. In principle one could detect collinearity by computing the determinant of $\mathbf{X}'\mathbf{X}$. The difficulty resides in analyzing situations where this determinant is very small but not zero. One possible strategy for detecting and removing collinearity is to go through a

process of orthogonalization of variables. (See Hendry [1995].)

Increasing the Number of Regressors

Increasing the number of regressors does not always improve regressions. The econometric theorem known as Pyrrho's lemma relates to the number of regressors. (See Dijkstra [1995].) Pyrrho's lemma states that by adding one special regressor to a linear regression, it is possible to arbitrarily change the size and sign of regression coefficients as well as to obtain an arbitrary goodness of fit. This result, rather technical, seems artificial as the regressor is an artificially constructed variable. It is, however, a perfectly rigorous result; it tells us that, if we add regressors without a proper design and testing methodology, we risk obtaining spurious results.

Pyrrho's lemma is the proof that modeling results can be arbitrarily manipulated in-sample even in the simple context of linear regressions. In fact, by adding regressors one might obtain an excellent fit in-sample though these regressors might have no predictive power out-of-sample. In addition, the size and even the sign of the regression relationships can be artificially altered in-sample.

The above observations are especially important for those financial models that seek to forecast prices, returns, or rates based on regressions over economic or fundamental variables. With modern computers, by trial and error, one might find a complex structure of regressions that give very good results in-sample but have no real forecasting power.

KEY POINTS

- In regression analysis, the relationship between a random variable, called the dependent variable, and one or more variables referred to as the independent variables, regressors, or explanatory variables (which can be random variables or deterministic variables) is estimated.
- Factorization, which involves expressing a joint density as a product of a marginal density and a conditional density, is the conceptual basis of financial econometrics.
- An econometric model is a probe that extracts independent samples—the noise terms—from highly dependent variables.
- Regressions have a twofold nature: they can be either (1) the representation of dependence in terms of conditional expectations and conditional distributions or (2) the representation of dependence of random variables on deterministic parameters.
- In many applications in financial modeling, the regressors are deterministic variables. Therefore, on a conceptual level, regressions with deterministic regressors are different from cases where regressors are random variables. In particular, a financial modeler cannot view the regression as a conditional expectation.
- There are two main estimation techniques for estimating the parameters of a regression: maximum likelihood method and ordinary least squares method. The maximum likelihood principle requires maximization of the log-likelihood function. The ordinary least squares method requires minimization of the sum of the squared residuals. The ordinary least squares estimators are the best linear unbiased estimators.
- Because the estimated regression parameters depend on the sample, they are random variables whose distribution is to be determined. The sampling distributions differ depending on whether the regressors are assumed to be fixed deterministic variables or random variables.
- A measure of the quality of approximation offered by a linear regression is given by the variance of the residuals. If residuals are large, the regression model has little explanatory power. However, the size of the average residual in itself is meaningless as it has to be

compared with the range of the variables. A widely used measure of the quality and usefulness of a regression model is given by the coefficient of determination, denoted by R^2 or R -squared, that can attain a value from zero to one. The adjusted R^2 is defined as R^2 corrected by a penalty function that takes into account the number of regressors in the model.

- Stepwise regression is a model-building technique for regression designs. The two methodologies for stepwise regression are the backward stepwise method and the backward removal method.
- A time series is said to be autocorrelated if each term is correlated with its predecessor so that the variance of each term is partially explained by regressing each term on its predecessor. Autocorrelation of residuals, a violation of the regression model assumptions, is quite common in financial estimation where financial modelers regress quantities that are time series. When there is autocorrelation present in a time series, the generalized least squares estimation method is used. The Durbin-Watson test or the Dickey-Fuller test can be utilized to gauge test for the presence of autocorrelation for the residuals.
- Three other situations where there are possible pitfalls of using regressions are spurious regressions with integrated variables, collinearity, and increasing the number of regressors. Spurious regressions occur when an apparently meaningful regression between variables that are independent is estimated. Collinearity occurs when two or more regressors in a regression model have a linear deterministic relationship.
- Pyrrho's lemma, which relates to the number of regressors in a regression model, states that by adding one special regressor to a linear regression, it is possible to arbitrarily change the size and sign of regression coefficients as

well as to obtain an arbitrary goodness of fit. Pyrrho's lemma is the proof that modeling results can be arbitrarily manipulated in-sample even in the simple context of linear regressions.

NOTES

1. The data were supplied by David Wright of Northern Illinois University.
2. We are grateful to Robert Scott of the Bank for International Settlement for suggesting this illustration and for providing the data.

Categorical and Dummy Variables in Regression Models

SERGIO M. FOCARDI, PhD
Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: In the application of regression analysis there are many situations where either the dependent variable or one or more of the regressors are categorical variables. When one or more categorical variables are used as regressors, a financial modeler must understand how to code the data, test for the significance of the categorical variables, and, based on the coding, how to interpret the estimated parameters. When the dependent variable is a categorical variable, the model is a probability model.

There are many times in the application of regression analysis when the financial modeler will need to include a categorical variable rather than a continuous variable as a regressor. *Categorical variables* are variables that represent group membership. For example, given a set of bonds, the rating is a categorical variable that indicates to what category—AA, BB, and so on—each bond belongs. A categorical variable does not have a numerical value or a numerical interpretation in itself. Thus the fact that a bond is in category AA or BB does not, in itself, measure any quantitative characteristic of the bond, though quantitative attributes such as a bond's yield spread can be associated with each category.

In this entry, we will discuss how to deal with regressors that are categorical variables in a regression model. There are also applications

where the dependent variable may be a categorical variable. For example, the dependent variable could be bankruptcy or nonbankruptcy of a company over some period of time. In such cases, the product of a regression is a probability. Probability models of this type include linear probability, logit regression, and probit linear models.

INDEPENDENT CATEGORICAL VARIABLES

Categorical input variables are used to cluster input data into different groups. That is, suppose we are given a set of input-output data and a partition of the data set in a number of subsets A_i so that each data point belongs to one and only one set. The A_i represent a categorical input variable. In financial econometrics

categories might represent, for example, different market regimes, economic states, ratings, countries, industries, or sectors.

We cannot, per se, mix quantitative input variables and categorical variables. For example, we cannot sum yield spreads and their ratings. However, we can perform a transformation that allows the mixing of categorical and quantitative variables. Let's see how. Suppose first that there is only one categorical input variable D , one quantitative input variable X , and one quantitative output variable Y . Consider our set of quantitative data, that is, quantitative observations. We organize data in a matrix form as usual:

$$Y = \begin{bmatrix} Y_1 \\ \vdots \\ Y_T \end{bmatrix}, X = \begin{bmatrix} 1 & X_{11} \\ \vdots & \vdots \\ 1 & X_{T1} \end{bmatrix}$$

Suppose data belong to two categories. An explanatory variable that distinguishes only two categories is called a dichotomous variable. The key is to represent a dichotomous categorical variable as a numerical variable D , called a *dummy variable*, that can assume the two values 0,1. We can now add the variable D to the input variables to represent membership in one or the other group:

$$X = \begin{bmatrix} D_1 & 1 & X_{11} \\ \vdots & \vdots & \vdots \\ D_T & 1 & X_{T1} \end{bmatrix}$$

If $D_i = 0$, the data X_i belong to the first category; if $D_i = 1$, the data X_i belong to the second category.

Consider now the regression equation

$$Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i$$

In financial econometric applications, the index i will be time or a variable that identifies a cross section of assets, such as bond issues. Consider that we can write three separate regression equations, one for those data that correspond to $D = 1$, one for those data that correspond to $D = 0$, and one for the fully pooled data. Suppose now that the three equations differ by the

intercept term but have the same slope. Let's explicitly write the two equations for those data that correspond to $D = 1$ and for those data that correspond to $D = 0$:

$$y_i = \begin{cases} \beta_{00} + \beta_1 X_i + \varepsilon_i, & \text{if } D_i = 0 \\ \beta_{01} + \beta_1 X_i + \varepsilon_i, & \text{if } D_i = 1 \end{cases}$$

where i defines the observations that belong to the first category when the dummy variable D assumes value 0 and also defines the observations that belong to the second category when the dummy variable D assumes value 1. If the two categories are recession and expansion, the first equation might hold in periods of expansion and the second in periods of recession. If the two categories are investment-grade bonds and noninvestment-grade bonds, the two equations apply to different cross sections of bonds, as will be illustrated in an example later in this entry.

Observe now that, under the assumption that only the intercept term differs in the two equations, the two equations can be combined into a single equation in the following way:

$$Y_i = \beta_{00} + \gamma D(i) + \beta_1 X_i + \varepsilon_i$$

where $\gamma = \beta_{01} - \beta_{00}$ represents the difference of the intercept for the two categories. In this way we have defined a single regression equation with two independent quantitative variables, X , D , to which we can apply all the usual tools of regression analysis, including the ordinary least squares (OLS) estimation method and all the tests. By estimating the coefficients of this regression, we obtain the common slope and two intercepts. Observe that we would obtain the same result if the categories were inverted. However, the interpretation of the estimated parameter for the categorical variable would differ depending on which category is omitted.

Thus far we have assumed that there is no interaction between the categorical and the quantitative variable, that is, the slope of the regression is the same for the two categories. This means that the effects of variables are additive; that is, the effect of one variable is added

regardless of the value taken by the other variable. In many applications, this is an unrealistic assumption.

Using dummy variables, the treatment is the same as that applied to intercepts. Consider the regression equation $Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i$ and write two regression equations for the two categories as we did above:

$$y_i = \begin{cases} \beta_0 + \beta_{10} X_i + \varepsilon_i, & \text{if } D_i = 0 \\ \beta_0 + \beta_{11} X_i + \varepsilon_i, & \text{if } D_i = 1 \end{cases}$$

We can couple these two equations in a single equation as follows:

$$Y_i = \beta_0 + \beta_{10} X_i + \delta(D_i X_i) + \varepsilon_i$$

where $\delta = \beta_{11} - \beta_{10}$. In fact, the above equation is identical to the first equation for $D_i = 0$ and to the second for $D_i = 1$. This regression can be estimated with the usual LS methods.

In practice, it is rarely appropriate to consider only interactions and not the intercept, which is the main effect. We call *marginalization* the fact that the interaction effect is marginal with respect to the main effect. However, we can easily construct a model that combines both effects. In fact we can write the following regression adding two variables, the dummy D and the interaction DX :

$$Y_i = \beta_0 + \gamma D_i + \beta_1 X_i + \delta(D_i X_i) + \varepsilon_i$$

This regression equation, which now includes three regressors, combines both effects.

The above process of introducing dummy variables can be generalized to regressions with multiple variables. Consider the following regression:

$$Y_i = \beta_0 + \sum_{j=1}^N \beta_j X_{ij} + \varepsilon_i$$

where data can be partitioned in two categories with the use of a dummy variable:

$$\mathbf{X} = \begin{bmatrix} D_1 & 1 & X_{11} & \cdots & X_{1N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ D_T & 1 & X_{T1} & \cdots & X_{TN} \end{bmatrix}$$

We can introduce the dummy D as well as its interaction with the N quantitative variable and

thus write the following equation:

$$Y_i = \beta_0 + \gamma_i D_i + \sum_{j=1}^N \beta_j X_{ij} + \sum_{j=1}^N \delta_{ij}(D_i X_{ij}) + \varepsilon_i$$

The above discussion depends critically on the fact that there are only two categories, a fact that allows one to use the numerical variable 0,1 to identify the two categories. However, the process can be easily extended to multiple categories by adding dummy variables. Suppose there are $K > 2$ categories. An explanatory variable that distinguishes between more than two categories is called a polytomous variable.

Suppose there are three categories, A , B , and C . Consider a dummy variable $D1$ that assumes a value one on the elements of A and zero on all the others. Let's now add a second dummy variable $D2$ that assumes the value one on the elements of the category B and zero on all the others. The three categories are now completely identified: A is identified by the values 1,0 of the two dummy variables, B by the values 0,1, and C by the values 0,0. Note that the values 1,1 do not identify any category. This process can be extended to any number of categories. If there are K categories, we need $K - 1$ dummy variables.

How can we determine if a given categorization is useful? It is quite obvious that many categorizations will be totally useless for the purpose of any econometric regression. If we categorize bonds in function of the color of the logo of the issuer, it is quite obvious that we obtain meaningless results. In other cases, however, distinctions can be subtle and important. Consider the question of market regime shifts or structural breaks. These are delicate questions that can be addressed only with appropriate statistical tests.

A word of caution about statistical tests is in order. Statistical tests typically work under the assumptions of the model and might be misleading if these assumptions are violated. If we try to fit a linear model to a process that is inherently nonlinear, tests might be misleading. It is good practice to use several tests and to

be particularly attentive to inconsistencies between test results. Inconsistencies signal potential problems in applying tests, typically model misspecification.

The t -statistic applied to the regression coefficients of dummy variables offer a set of important tests to judge which regressors are significant. The t -statistics are the coefficients divided by their respective squared errors. The p -value associated with each coefficient estimate is the probability of the hypothesis that the corresponding coefficient is zero, that is, that the corresponding variable is irrelevant.

We can also use the F -test to test the significance of each specific dummy variable. To do so we can run the regression with and without that variable and form the corresponding F -test. The *Chow test* is the F -test to gauge if all the dummy variables are collectively irrelevant (see Chow, 1960). The Chow test is an F -test of mutual exclusion, written as follows:

$$F = \frac{[SSR - (SSR_1 + SSR_2)] [n - 2(k + 1)]}{SSR_1 + SSR_2} \frac{1}{k + 1}$$

where

SSR_1 = the squared sum of residuals of the regression run with data in the first category without dummy variables

SSR_2 = the squared sum of residuals of the regression run with data in the second category without dummy variables

SSR = the squared sum of residuals of the regression run with fully pooled data without dummy variables

Observe that $SSR_1 + SSR_2$ is equal to the squared sum of residuals of the regression run on fully pooled data but with dummy variables. Thus the Chow test is the F -test of the unrestricted regressions with and without dummy variables.

Illustration: Predicting Corporate Bond Yield Spreads

To illustrate the use of dummy variables, we will estimate a model to predict corporate bond spreads.¹ The regression is relative to a cross section of bonds. The regression equation is the following:

$$\text{Spread}_i = \beta_0 + \beta_1 \text{Coupon}_i + \beta_2 \text{CoverageRatio}_i + \beta_3 \text{LoggedEBIT}_i + \varepsilon_i$$

where

Spread_i = option-adjusted spread (in basis points) for the bond issue of company i

Coupon_i = coupon rate for the bond of company i , expressed without considering percentage sign (i.e., 7.5% = 7.5)

CoverageRatio_i = earnings before interest, taxes, depreciation and amortization (EBITDA) divided by interest expense for company i

LoggedEBIT_i = logarithm of earnings (earnings before interest and taxes, EBIT, in millions of dollars) for company i

The dependent variable, Spread, is not measured by the typically nominal spread but by the option-adjusted spread. This spread measure adjusts for any embedded options in a bond (see Chapter 6 in Fabozzi, 2006).

Theory would suggest the following properties for the estimated coefficients:

- The higher the coupon rate, the greater the issuer's default risk and hence the larger the spread. Therefore, a positive coefficient for the coupon rate is expected.
- A coverage ratio is a measure of a company's ability to satisfy fixed obligations, such as interest, principal repayment, or lease payments. There are various coverage ratios. The one used in this illustration is the ratio of the earnings before interest, taxes,

depreciation, and amortization (EBITDA) divided by interest expense. Since the higher the coverage ratio the lower the default risk, an inverse relationship is expected between the spread and the coverage ratio; that is, the estimated coefficient for the coverage ratio is expected to be negative.

- There are various measures of earnings reported in financial statements. Earnings in this illustration is defined as the trailing 12-months earnings before interest and taxes (EBIT). Holding other factors constant, it is expected that the larger the EBIT, the lower the default risk and therefore an inverse relationship (negative coefficient) is expected.

We used 100 observations at two different dates, 6/6/05 and 11/28/05; thus there are 200 observations in total. This will allow us to test if there is a difference in the spread regression for investment-grade and noninvestment grade bonds using all observations. We will then test to see if there is any structural break between the two dates. We organize the data in matrix form as usual. Data are shown in Table 1. The second column indicates that data belong to two categories and suggests the use of one dummy variable. Another dummy variable is used later to distinguish between the two dates. Let's first estimate the regression equation for the fully pooled data, that is, all data without any distinction in categories. The estimated coefficients for the model and their corresponding *t*-statistics are shown below:

Coefficient	Estimated Coefficient	Standard Error	<i>t</i> -statistic	<i>p</i> -value
β_0	157.01	89.56	1.753	0.081
β_1	61.27	8.03	7.630	9.98E-13
β_2	-13.20	2.27	-5.800	2.61E-08
β_3	-90.88	16.32	-5.568	8.41E-08

Other regression results are:

SSR: 2.3666e + 006
F-statistic: 89.38
p-value: 0
*R*²: 0.57

Given the high value of the *F*-statistic and the *p*-value close to zero, the regression is significant. The coefficient for the three regressors is statistically significant and has the expected sign. However, the intercept term is not statistically significant. The residuals are given in the first column of Table 2.

Let's now analyze if we obtain a better fit if we consider the two categories of investment-grade and below investment-grade bonds. It should be emphasized that this is only an exercise to show the application of regression analysis. The conclusions we reach are not meaningful from an econometric point of view given the small size of the database. The new equation is written as follows:

$$\text{Spread}_i = \beta_0 + \beta_1 D1_i + \beta_2 \text{Coupon}_i + \beta_3 D1_i \text{Coupon}_i + \beta_4 \text{CoverageRatio}_i + \beta_5 D1_i \text{CoverageRatio}_i + \beta_6 \text{LoggedEBIT}_i + \beta_7 D1_i \text{LoggedEBIT}_i + \varepsilon_i$$

There are now seven variables and eight parameters to estimate. The estimated model coefficients and the *t*-statistics are shown below:

Coefficient	Estimated Coefficient	Standard Error	<i>t</i> -statistic	<i>p</i> -value
β_0	284.52	73.63	3.86	0.00
β_1	597.88	478.74	1.25	0.21
β_2	37.12	7.07	5.25	3.96E-07
β_3	-45.54	38.77	-1.17	0.24
β_4	-10.33	1.84	-5.60	7.24E-08
β_5	50.13	40.42	1.24	0.22
β_6	-83.76	13.63	-6.15	4.52E-09
β_7	-0.24	62.50	-0.00	1.00

Other regression results are:

SSR: 1.4744e + 006
F-statistic: 76.83
p-value: 0
*R*²: 0.73

The Chow test has the value 16.60. The *F*-statistic and the Chow test suggest that the use of dummy variables has greatly improved the goodness of fit of the regression, even after compensating for the increase in the number of

Table 1 Regression Data for the Bond Spread Application: 11/28/2005 and 06/06/2005

Notes:

Spread = option-adjusted spread (in basis points)

Coupon = coupon rate, expressed without considering percentage sign (i.e., 7.5% = 7.5)

Coverage Ratio = EBITDA divided by interest expense for company

Logged EBIT = logarithm of earnings (EBIT in millions of dollars)

Notes:

Residuals: residuals from the pooled regression without dummy variables for investment grade.

Residuals Dummy 1: inclusion of dummy variable for investment grade.

Residuals Dummy 2: inclusion of dummy variable to test for regime shift.

parameters. The residuals of the model without and with dummy variable D1 are shown, respectively, in the second and third columns of Table 2.

Now let's use dummy variables to test if there is a regime shift between the two dates. This is a common use for dummy variables in practice. To this end we create a new dummy variable that has the value 0 for the first date 11/28/05

and 1 for the second date 6/6/05. The new equation is written as follows:

$$\begin{aligned}
 \text{Spread}_i = & \beta_0 + \beta_1 D2_i + \beta_2 \text{Coupon}_i \\
 & + \beta_3 D2_i \text{Coupon}_i + \beta_4 \text{CoverageRatio}_i \\
 & + \beta_5 D2_i \text{CoverageRatio}_i + \beta_6 \text{LoggedEBIT}_i \\
 & + \beta_7 D2_i \text{LoggedEBIT}_i + \varepsilon_i
 \end{aligned}$$

as in the previous case but with a different dummy variable. There are seven independent

variables and eight parameters to estimate. The estimated model coefficients and t -statistics are shown below:

Coefficient	Estimated Coefficient	Standard Error	t -statistic	p -value
β_0	257.26	79.71	3.28	0.00
β_1	82.17	61.63	1.33	0.18
β_2	33.25	7.11	4.67	5.53E-06
β_3	28.14	2.78	10.12	1.45E-19
β_4	-10.79	2.50	-4.32	2.49E-05
β_5	0.00	3.58	0.00	1.00
β_6	-63.20	18.04	-3.50	0.00
β_7	-27.48	24.34	-1.13	0.26

Other regression statistics are:

SSR: 1.5399e + 006

F -statistic: 72.39

p -value: 0

R^2 : 0.71

The Chow test has the value 14.73. The F -statistics and the Chow test suggest that there is indeed a regime shift and that the spread regressions at the two different dates are different. Again, the use of dummy variables has greatly improved the goodness of fit of the regression, even after compensating for the increase in the number of parameters. The residuals of the model with dummy variables D2 are shown in the next-to-the-last column of Table 2.

Illustration: Testing the Mutual Fund Characteristic Lines in Different Market Environments

The characteristic line of a mutual fund is the regression of the excess returns of a mutual fund on the market's excess returns:

$$y_{it} = \alpha_i + \beta_i x_t$$

where

y_{it} = mutual fund i 's excess return over the risk-free rate

x_t = market excess return over the risk-free rate

α_i and β_i = the regression parameters to be estimated for mutual fund i

We will first estimate the characteristic line for two large-cap mutual funds. Since we would prefer not to disclose the name of each fund, we simply refer to them as A and B. (Neither mutual fund selected is an index fund.) Because the two mutual funds are large-cap funds, the S&P 500 was used as the benchmark. The risk-free rate used was the 90-day Treasury bill rate. Ten years of monthly data were used from January 1, 1995 to December 31, 2004. The data are reported in Table 3. The first column in the table shows the month. The second and third columns give the return on the market return (r_{Mt}) and risk-free rate (r_{ft}), respectively. The fifth column is the excess market return, which is x_t in the regression equation. The seventh and eighth columns show the returns for mutual funds A and B, respectively. The excess returns for the two mutual funds (y_{it}) are given in the last two columns. The other columns will be explained shortly.

The results of the above regression for both mutual funds are shown in Table 4. The estimated β for both mutual funds is statistically significantly different from zero.

Let's now perform a simple application of the use of dummy variables by determining if the slope (beta) of the two mutual funds is different in a rising stock market ("up market") and a declining stock market ("down market"). To test this, we can write the following multiple regression model:

$$y_{it} = \alpha_i + \beta_{1i}x_t + \beta_{2i}(D_t x_t) + e_{it}$$

where D_t is the dummy variable that can take on a value of 1 or 0. We will let

$D_t = 1$ if period t is classified as an up market

$D_t = 0$ if period t is classified as a down market

The coefficient for the dummy variable is β_{2i} . If that coefficient is statistically significant, then for the mutual fund:

In an up market: $\beta_i = \beta_{1i} + \beta_{2i}$

In a down market: $\beta_i = \beta_{1i}$

12/31/2004	3.40	0.16	1	3.24	3.24	2.62	3.43	2.46	3.27

Notes:

1. The following information is used for determining the value of the dummy variable for the first three months:

	r_m	r_f	$r_m - r_f$
Sep-94	-2.41	0.37	-2.78
Oct-94	2.29	0.38	1.91
Nov-94	-3.67	0.37	-4.04
Dec-94	1.46	0.44	1.02

2. The dummy variable is defined as follows:

$$D_t x_t = x_t \text{ if } (r_M - r_{ft}) \text{ for the prior three months } > 0$$

$$D_t x_t = 0 \text{ otherwise}$$

If β_{2i} is not statistically significant, then there is no difference in β_i for up and down markets.

In our illustration, we have to define what we mean by an up and a down market. We will

define an up market precisely as one where the average excess return (market return over the risk-free rate or $(r_{Mt} - r_{ft})$) for the prior three months is greater than zero. Then

$$D_t = 1 \text{ if the average } (r_{Mt} - r_{ft}) \text{ for the prior three months } > 0$$

$$D_t = 0 \text{ otherwise}$$

The regressor will then be

$$D_t x_t = x_t \text{ if } (r_{Mt} - r_{ft}) \text{ for the prior three months } > 0$$

$$D_t x_t = 0 \text{ otherwise}$$

The data are presented in Table 3. The fourth column provides the coding for the dummy variable, D_t , and the sixth column shows the

Table 4 Characteristic Line for Mutual Funds A and B

	Coefficient Estimate	Standard Error	t -statistic ^a	p -value
Mutual Fund A				
α	0.206	0.102	-2.014	0.046
β	0.836	0.022	37.176	0.000
R_2	0.92			
p -value	0.000			
Mutual Fund B				
α	0.010	0.140	0.073	0.942
β	0.816	0.031	26.569	0.000
R_2	0.86			
p -value	0.000			

^aNull hypothesis is that β is equal to zero.

Table 5 Regression Results for Dummy Variable Regression for Mutual Funds A and B

	Coefficient	Standard		
Coefficient	Estimate	Error	<i>t</i> -statistic	<i>p</i> -value
Fund A				
α	-0.23	0.10	-2.36	0.0198
β_1	0.75	0.03	25.83	4E-50
β_2	0.18	0.04	4.29	4E-05
Fund B				
α	0.00	0.14	-0.03	0.9762
β_1	0.75	0.04	18.02	2E-35
β_2	0.13	0.06	2.14	0.0344

product of D_t and x_t . The regression results for the two mutual funds are shown in Table 5. The adjusted R^2 is 0.93 and 0.83 for mutual funds A and B, respectively.

For both funds, β_{2i} is statistically significantly different from zero. Hence, for these two mutual funds, there is a difference in the β_i for up and down markets. From the results reported previously, we would find that:

	Mutual Fund A	Mutual Fund B
Down market $\beta_i (= \beta_{1i})$	0.75	0.75
Up market $\beta_i (= \beta_{1i} + \beta_{2i})$	0.93 (= 0.75 + 0.18)	0.88 (= 0.75 + 0.13)

DEPENDENT CATEGORICAL VARIABLES

Thus far we have discussed models where the independent variables can be either quantitative or categorical while the dependent variable is quantitative. Let's now discuss models where the *dependent variable* is categorical. Recall that a regression model can be interpreted as a conditional probability distribution. Suppose that the dependent variable is a categorical variable Y that can assume two values, which we represent conventionally as 0 and 1. The probability distribution of the dependent variable is then a discrete function:

$$\begin{cases} P(Y = 1) = p \\ P(Y = 0) = q = 1 - p \end{cases}$$

A regression model where the dependent variable is a categorical variable is therefore a probability model; that is, it is a model of the probability p given the values of the independent variables \mathbf{X} :

$$P(Y = 1|\mathbf{X}) = f(\mathbf{X})$$

In the following sections we will discuss three probability models: the linear probability model, the probit regression model, and the logit regression model.

Linear Probability Model

The *linear probability model* assumes that the function $f(\mathbf{X})$ is linear. For example, a linear probability model of default assumes that there is a linear relationship between the probability of default and the factors that determine default.

$$P(Y = 1|\mathbf{X}) = f(\mathbf{X})$$

The parameters of the model can be obtained by using ordinary least squares applying the estimation methods of multiple regression models entry. Once the parameters of the model are estimated, the predicted value for $P(Y)$ can be interpreted as the event probability such as the probability of default in our previous example. Note, however, that when using a linear probability model, in this entry the R^2 is used only if all the independent variables are also binary variables.

A major drawback of the linear probability model is that the predicted value may be negative. In the probit regression and logit regression models described below, the predicted probability is forced to be between 0 and 1.

Probit Regression Model

The *probit regression model* is a nonlinear regression model where the dependent variable is a binary variable. Due to its nonlinearity, one cannot estimate this model with least squares methods. We have to use maximum likelihood (ML) methods as described below.

Because what is being predicted is the standard normal cumulative probability distribution, the predicted values are between 0 and 1.

The general form for the probit regression model is

$$P(Y = 1 | X_1, X_2, \dots, X_K) = N(a + b_1 X_1 + b_2 X_2 + \dots + b_K X_K)$$

where N is the cumulative standard normal distribution function.

To see how ML methods work, consider a model of the probability of corporate bond defaults. Suppose that there are three factors that have been found to historically explain corporate bond defaults. The probit regression model is then

$$\begin{cases} P(Y = 1 | X_1, X_2, X_3) \\ = N(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3) \\ P(Y = 0 | X_1, X_2, X_3) \\ = 1 - N(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3) \end{cases}$$

The likelihood function is formed from the products

$$\prod_i N(\beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{3i})^{Y_i} (1 - N(\beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \beta_3 X_{3i}))^{1 - Y_i}$$

extended to all the samples, where the variable Y assumes a value of 0 for defaulted companies and 1 for nondefaulted companies. Parameters are estimated by maximizing the likelihood.

Suppose that the following parameters are estimated:

$$\beta = -2.1 \quad \beta_1 = 1.9 \quad \beta_2 = 0.3 \quad \beta_3 = 0.8$$

Then

$$N(a + b_1 X_1 + b_2 X_2 + b_3 X_3) = N(-2.1 + 1.9X_1 + 0.3X_2 + 0.8X_3)$$

Now suppose that the probability of default of a company with the following values for the

independent variables is sought:

$$X_1 = 0.2 \quad X_2 = 0.9 \quad X_3 = 1.0$$

Substituting these values we get

$$N(-2.1 + 1.9(0.2) + 0.3(0.9) + 0.8(1.0)) = N(-0.65)$$

The standard normal cumulative probability for $N(-0.65)$ is 25.8%. Therefore, the probability of default for a company with this characteristic is 25.8%.

Application to Hedge Fund Survival

An illustration of the probit regression model is provided by Malkiel and Saha (2005) who use it to calculate the probability of the demise of a hedge fund. The dependent variable in the regression is 1 if a fund is defunct (did not survive) and 0 if it survived. The explanatory variables, their estimated coefficient, and the standard error of the coefficient using hedge fund data from 1994 to 2003 are given below:

Explanatory Variable	Coefficient	Standard Deviation
1. Return for the first quarter before the end of fund performance	-1.47	0.36
2. Return for the second quarter before the end of fund performance	-4.93	0.32
3. Return for the third quarter before the end of fund performance	-2.74	0.33
4. Return for the fourth quarter before the end of fund performance	-3.71	0.35
5. Standard deviation for the year prior to the end of fund performance	17.76	0.92
6. Number of times in the final three months the fund's monthly return fell below the monthly median of all funds in the same primary category	0.00	0.33
7. Assets of the fund (in billions of dollars) estimated at the end of performance	-1.30	-7.76
Constant term	-0.37	0.07

For only one explanatory variable, the sixth one, the coefficient is not statistically significant from zero. That explanatory variable is a proxy for peer comparison of the hedge fund versus similar hedge funds. The results suggest that there is a lower probability of the demise of a hedge fund if there is good recent performance (the negative coefficient of the first four variables above) and the more assets under management (the negative coefficient for the last variable above). The greater the hedge fund performance return variability, the higher the probability of demise (the positive coefficient for the fifth variable above).

Logit Regression Model

As with the probit regression model, the *logit regression model* is a nonlinear regression model where the dependent variable is a binary variable and the predicted values are between 0 and 1. The predicted value is also a cumulative probability distribution. However, rather than being a standard normal cumulative probability distribution, it is a standard cumulative probability distribution of a distribution called the *logistic distribution*.

The general formula for the logit regression model is

$$\begin{aligned} P(Y = 1 | X_1, X_2, \dots, X_N) \\ &= F(a + b_1 X_1 + b_2 X_2 + \dots + b_N X_N) \\ &= -1/1 + e^{-W} \end{aligned}$$

where $W = a + b_1 X_1 + b_2 X_2 + \dots + b_N X_N$.

As with the probit regression model, the logit regression model is estimated with ML methods.

Using our previous illustration, $W = -0.65$. Therefore

$$1/[1 + e^{-W}] = 1/[1 + e^{-(-0.65)}] = 34.3\%$$

The probability of default for the company with these characteristics is 34.3%.

KEY POINTS

- Categorical variables are variables that represent group membership and can appear in a regression equation as a regressor or as an independent variable.
- A dichotomous variable is an explanatory variable that distinguishes only two categories; the key is to represent a dichotomous categorical variable as a numerical variable, referred to as a dummy variable, that can assume the two values 0,1.
- When a dummy variable is a regressor, the *t*-statistic can be used to determine if that variable is statistically significant. The Chow test can also be used to test if all the dummy variables in a regression model are collectively relevant.
- A regression model where the dependent variable is a categorical variable is a probability model, and there are three types of such models: the probability model, the probit regression model, and the logit regression model.
- The linear probability model assumes that the probability model to be estimated is linear and can be estimated using least squares.
- The probit regression model is a nonlinear regression model where the dependent variable is a binary variable. The model cannot be estimated using least squares because it is a nonlinear model and is instead estimated using maximum likelihood methods.
- The logit regression model is a nonlinear regression model where the dependent variable is a binary variable and the predicted values are between 0 and 1 and represent a cumulative probability distribution. Rather than being a standard normal cumulative probability distribution, it is a standard cumulative probability of a logit.

NOTE

1. The model presented in this illustration was developed by FridsonVision and is described in "Focus Issues Methodology," *Leverage World* (May 30, 2003). The data for this illustration were provided by Greg Braylovskiy of FridsonVision. The firm uses about 650 companies in its analysis. Only 100 observations were used in this illustration.

Quantile Regression

CHRIS GOWLLAND, CFA

Senior Quantitative Analyst, Delaware Investments

Abstract: Many of the statistical methods that are most commonly used by researchers and practitioners in finance are mainly focused on identifying the central tendency within a data set. However, there are numerous situations where it may be equally or more important to understand the dispersion between outcomes that are higher or lower than the central tendency. One statistical method that can be useful in such investigations is quantile regression, which conceptually can be viewed as a logical extension of ordinary least squares methods.

Many investors use regression methods to gauge the relative attractiveness of different firms, the risks inherent in active or passive portfolios, the historical performance of investment factors, and similar topics. Such research often focuses on understanding the “central tendency” within a data set, and for this purpose perhaps the most commonly used tool is regression based on *ordinary least squares* (OLS) approaches. OLS methods are designed to find the “line of best fit” by minimizing the sum of squared errors from individual data points. OLS analysis generally does a good job of describing the *central tendency* within a data set, but typically will be much less effective at describing the behavior of data points that are distant from the line of best fit. *Quantile regressions*, however, can be useful in such investigations. This statistical approach can be viewed conceptually as a logical extension of ordinary least squares methods. We present a brief

overview of quantile regression approaches, together with some examples of how such methods can be applied in practical situations.

COMPARING QUANTILE AND OLS APPROACHES

Conceptually, OLS *statistical analysis* can be summarized by the following equation, as expressed in a univariate context where a single independent variable is being used to explain or predict a single dependent variable:

$$Y_i = \alpha + \sum_{i=1}^N \beta X_i + \varepsilon$$

where Y represents the dependent variable, X represents the observed value of an independent variable, $i = 1, \dots, N$ data points, α represents the intercept (in other words, the value on the vertical axis when the horizontal axis is

The material discussed here does not necessarily represent the opinions, methods, or views of Delaware Investments.

zero), β represents the slope of the relationship between X and Y , and ε is an error term with an expected mean value of zero.

As a hypothetical example, suppose that X reflects the expected dividend in dollars for a universe of firms, and Y represents the stock price for each of those firms. Then the value of β will reflect the value that the market is assigning to each \$1 of dividend payment, while the value of α will reflect the expected price of a stock that does not pay a dividend. (Please note that we are not proposing that such an equation would provide a usable investment thesis.) It is possible to adapt this simple OLS equation to a multivariate context, in which several different independent variables are being used together to explain or predict the value of the dependent variable.

Similarly, quantile regression approaches can be summarized by the following equation, again in a univariate context:

$$Y_i = \alpha^p + \sum_{i=1}^N \beta^p X_i + \varepsilon^p$$

where α^p represents the intercept for a specified quantile, β^p represents the slope of the relationship between X and Y for a specified quantile, and ε^p similarly represents the error term for that specified quantile. (The specific form for these two equations has been adapted from Meligkotsidou, Vrontos, and Vrontos, 2007; other authors might use different terminology, but the underlying concepts are the same.) And just as OLS methods can be used in both univariate and multivariate contexts, the same is true for quantile regression approaches.

In this context, what is a quantile? It is a generalized form of a percentile, in other words a measure of spread between the highest and lowest values in a particular range. A quantile can conveniently be expressed in terms of percentages, so that the median will be the 50th quantile. But the same method can be used for any quantile, not just the 50th quantile. In this sense, quantile methods are somewhat similar

to value-at-risk (VaR) approaches, which seek to measure the “95th percentile” or “99th percentile” of potential losses in a portfolio.

REASONS FOR USING QUANTILE METHODS

If a data set is distributed in an approximately normal fashion, and if the analysis focuses specifically on the 50th quantile, then the results will often be quite similar to those derived from conventional OLS analysis. However, OLS methods tend to provide unreliable results if a data set is skewed, has “fat tails,” or has some extreme *outliers*—any or all of which can exist when the relevant data are drawn from economics or finance (Koenker and Hallock, 2001). In such circumstances, quantile regression focusing on the 50th quantile will often provide a more robust estimate of the central tendency than would be available from OLS approaches. Figure 1 provides a hypothetical example of a situation where quantile regression might be useful.

Figure 1 shows a scatter plot of a hypothetical relationship that has three main traits: (1) positive slope, (2) higher dispersion of results when the independent variable is small, and (3) a single outlier toward the top end of the range. The graph shows that the outlier exerts considerable influence on the OLS analysis by tending to skew the relationship upward. A conventional OLS approach might decide to exclude the outlier, but this would effectively mean throwing away the information contained in that data point. By contrast, the quantile analysis includes the outlier, but is less affected by its presence. As a consequence, quantile regression does a better job of identifying the “central tendency” within this data set—in exactly the same way as an analyst might choose to use the *median* rather than the mean when describing a distribution that has a heavy weight in the left or right tail.

The above analysis shows that quantile regression is more robust than OLS methods in

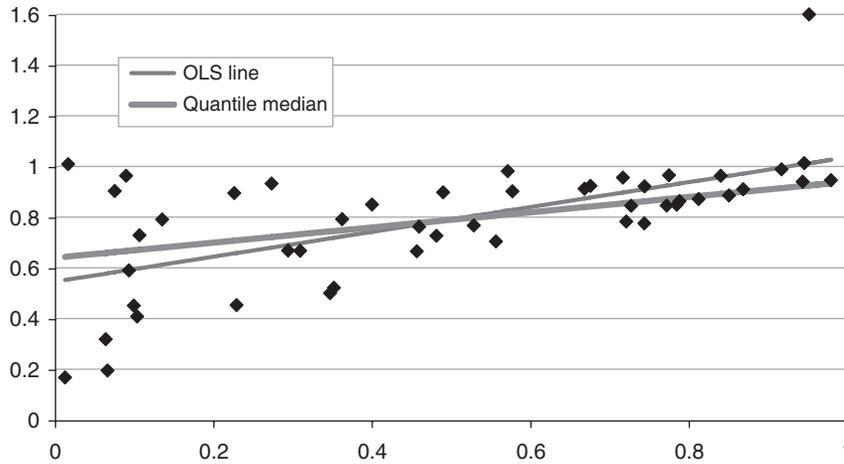

Figure 1 Effect of Outliers on OLS and Quantile Analysis
Note: Data are hypothetical and based on a simulated relationship.

the presence of outliers and other potentially distorting influences. Another useful feature of quantile approaches is that they allow analysis of areas away from the middle of the distribution. Conventional regression techniques focus on the “central tendency” of the data, and thus tend to prioritize describing the relationship that is most representative of the average. However, from the perspective of an active investor or a risk manager, the most interesting information may well be in the tails of the dis-

tribution, where the standard OLS approaches are not generally very informative, but where quantile methods can be readily applied.

Figure 2 shows the same scatter plot as Figure 1, but instead of showing the quantile median, it shows estimated lines for the 10th and 90th quantiles. The lines form a funnel-like shape, indicating that there is greater variation on the left of the distribution than the right. From the perspective of an investor, this suggests that the range of possible outcomes from

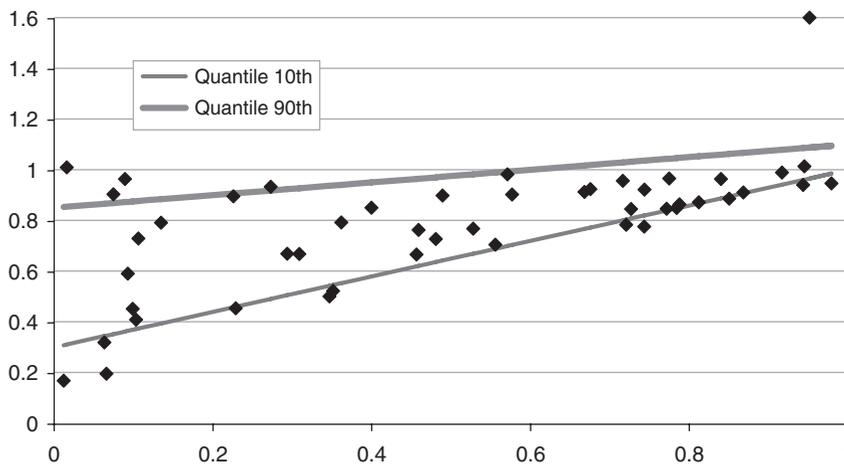

Figure 2 Effect of Outliers on OLS and Quantile Analysis: Estimated Lines for the 10th and 90th Quantiles
Note: Data are hypothetical and based on a simulated relationship.

investing in companies on the left of the distribution may be larger, and thus require more careful analysis. From the perspective of a risk manager, the difference in slope between the 10th and 90th percentiles might suggest that greater provisioning would be appropriate if a portfolio tends to have greater weight in the left of the distribution. Once again, the outlier is included in the analysis, but its impact on the estimated intercept and slope for the 10th and 90th percentiles is considerably muted by comparison with what would be expected using OLS-like methods.

BACKGROUND AND FURTHER EXAMPLES

Quantile regression methods were first developed in the 1970s in the discipline of statistics (Koenker and Bassett, 1978). Koenker (2005) provides a comprehensive overview of quantile regression in general, with numerous examples drawn from finance and from other subject areas. The statistical packages R, S-Plus, Stata, SAS, and SPSS all have quantile regression capabilities, either as part of their base distribution or as separate modules. These packages typically focus on linear quantile regression, but extensions to nonlinear applications are also feasible (Koenker and Hallock, 2001).

In recent years, quantile regression methods have become increasingly popular in finance and economics. Chernozhukov and Umantsev (2000) applied quantile methods to estimate VaR, noting that the basic structure could be applied to various possible modeling approaches. Wu and Xiao (2002) also used quantile methods to estimate VaR and provided an example of how such approaches could be used in the context of an index fund. Engle and Manganelli (2004) provided an example of how to use quantile regression approaches in calculating a conditional VaR measure. Kuester, Mittnik, and Paolella (2006) proposed extending the conditional VaR approach by incorporating some additional autoregressive elements.

An important area of research for academics and practitioners has been the influence of investment style on portfolio returns. One way to perform such analysis is through the analysis of portfolio holdings, but these are typically only available periodically and with a considerable lag. Another approach has been to focus on portfolio returns, which may be available at higher frequency and with a smaller delay. Early work in this area, such as Sharpe (1992) and Carhart (1997), generally relied on OLS approaches, which led to a focus on a portfolio's "central tendency" relative to its benchmark. Bassett and Chen (2001) extended this earlier work by applying quantile methods, and showed that this permits examination of active performance during periods when the portfolio and/or its benchmark are far away from their central tendency.

As shown above, quantile regression provides a more complete picture than OLS approaches of the conditional relationship among financial variables. Landajo, de Andrés, and Lorca (2008) used quantile methods to gauge the relationship between size and profitability for publishing firms in Spain, and showed that the patterns for small firms were rather different from those for their larger peers. Similarly, Lee, Chan, Yeh, and Chan (2010) used quantile methods on a sample of firms from Taiwan in order to assess how increasing internationalization affects relative valuation.

Quantile methods can also be used to test whether the quantile-specific parameters are stable over different quantiles and over time, as noted by Koenker and Xiao (2006). Quantile models can thus demonstrate how different variables affect the location, scale, and shape of the conditional distribution of the response. Such methods therefore constitute a significant extension of classical constant coefficient time series models, in which the effect of conditioning is typically confined to a shift of the intercept and/or the slope of the central tendency. Fatouh, Scaramozzino, and Harris (2005) used quantile methods to analyze how the capital structure of firms in Korea had changed

over time. Billett and Xue (2008) used quantile approaches to analyze the motivations behind open market share repurchases, and found that firms are generally more likely to repurchase shares when they are at higher risk of being taken over. Pires, Pereira, and Martins (2010) use quantile methods to analyze the determinants of credit default swap spreads over time, and report that some previously reported anomalous results may have occurred due to the emphasis on the conditional mean of the distribution, rather than on the upper and lower tails.

KEY POINTS

- Quantile regression methods are well established in the statistical literature, and are increasingly being used in finance.
- Quantile regression methods are more robust than conventional OLS approaches to skewed distributions, fat tails, and the presence of outliers—all of which are frequently encountered in real-world financial data.
- Quantile regression approaches can be used to assess the central tendency of a data set, and in this sense can be viewed as a regression-based analogue of the median of a distribution. The same approaches can also be used to examine the upper or lower reaches of a data set, which is not possible using conventional OLS methods.
- For active investors and risk managers, the upper or lower tails of a distribution may well be more interesting than the central tendency, and quantile regression is an appropriate tool for such work.
- Quantile regression methods can be applied to data from a single period, but can also be applied in a time-series context. Such methods can help in analyzing how relationships may have changed over time.

Abstract: Volatility is a key parameter used in many financial applications, from derivatives valuation to asset management and risk management. Volatility measures the size of the errors made in modeling returns and other financial variables. It was discovered that, for vast classes of models, the average size of volatility is not constant but changes with time and is predictable. Autoregressive conditional heteroskedasticity (ARCH), generalized autoregressive conditional heteroskedasticity (GARCH) models, and stochastic volatility models are the main tools used to model and forecast volatility. Moving from single assets to portfolios made of multiple assets, not only are there idiosyncratic volatilities but also correlations and covariances between assets that are time varying and predictable. Multivariate ARCH/GARCH models and dynamic factor models, eventually in a Bayesian framework, are the basic tools used to forecast correlations and covariances.

In this entry we discuss the modeling of the time behavior of the uncertainty related to many econometric models when applied to financial data. Finance practitioners know that errors made in predicting markets are not of a constant magnitude. There are periods when unpredictable market fluctuations are larger and periods when they are smaller. This behavior, known as *heteroskedasticity*, refers to the fact that the size of market *volatility* tends to cluster in periods of high volatility and periods of

low volatility. The discovery that it is possible to formalize and generalize this observation was a major breakthrough in econometrics. In fact, we can describe many economic and financial data with models that predict, simultaneously, the economic variables and the average magnitude of the squared prediction error.

In this entry, we show how the average error size can be modeled as an autoregressive process. Given their autoregressive nature, these

models are called *autoregressive conditional heteroskedasticity (ARCH)* or *generalized autoregressive conditional heteroskedasticity (GARCH)*. This discovery is particularly important in financial econometrics, where the error size is, in itself, a variable of great interest.

REVIEW OF LINEAR REGRESSION AND AUTOREGRESSIVE MODELS

Let's first discuss two examples of basic econometric models, the *linear regression model* and the *autoregressive model*, and illustrate the meaning of homoskedasticity or heteroskedasticity in each case.

The linear regression model is the workhorse of economic modeling. A univariate linear regression represents a proportionality relationship between two variables:

$$y = \alpha + \beta x + \varepsilon$$

The preceding linear regression model states that the expectation of the variable y is β times the expectation of the variable x plus a constant α . The proportionality relationship between y and x is not exact but subject to an error ε .

In standard regression theory, the error ε is assumed to have a zero mean and a constant standard deviation σ . The standard deviation is the square root of the variance, which is the expectation of the squared error: $\sigma^2 = E(\varepsilon^2)$. It is a positive number that measures the size of the error. We call *homoskedasticity* the assumption that the expected size of the error is constant and does not depend on the size of the variable x . We call *heteroskedasticity* the assumption that the expected size of the error term is not constant.

The assumption of homoskedasticity is convenient from a mathematical point of view and is standard in regression theory. However, it is an assumption that must be verified empirically. In many cases, especially if the range of variables is large, the assumption of homo-

skedasticity might be unreasonable. For example, assuming a linear relationship between consumption and household income, we can expect that the size of the error depends on the size of household income. In fact, high-income households have more freedom in the allocation of their income.

In the preceding household-income example, the linear regression represents a cross-sectional model without any time dimension. However, in finance and economics in general, we deal primarily with time series, that is, sequences of observations at different moments of time. Let's call X_t the value of an economic time series at time t . Since the groundbreaking work of Haavelmo (1944), economic time series are considered to be realizations of stochastic processes. That is, each point of an economic time series is considered to be an observation of a random variable.

We can look at a stochastic process as a sequence of variables characterized by joint-probability distributions for every finite set of different time points. In particular, we can consider the distribution f_t of each variable X_t at each moment. Intuitively, we can visualize a stochastic process as a very large (infinite) number of paths. A process is called weakly stationary if all of its second moments are constant. In particular this means that the mean and variance are constants $\mu_t = \mu$ and $\sigma_t^2 = \sigma^2$ that do not depend on the time t . A process is called strictly stationary if none of its finite distributions depends on time. A strictly stationary process is not necessarily weakly stationary as its finite distributions, though time-independent, might have infinite moments.

The terms μ_t and σ_t^2 are the unconditional mean and variance of a process. In finance and economics, however, we are typically interested in making forecasts based on past and present information. Therefore, we consider the distribution $f_{t_2}(x | I_{t_1})$ of the variable X_{t_2} at time t_2 conditional on the information I_{t_1} known at time t_1 . Based on information available at time $t - 1$, I_{t-1} , we can also define the

conditional mean and the conditional variance $(\mu_t | I_{t-1})$, $(\sigma_t^2 | I_{t-1})$.

A process can be weakly stationary but have time-varying conditional variance. If the conditional mean is constant, then the unconditional variance is the unconditional expectation of the conditional variance. If the conditional mean is not constant, the unconditional variance is not equal to the unconditional expectation of the conditional variance; this is due to the dynamics of the conditional mean.

In describing ARCH/GARCH behavior, we focus on the error process. In particular, we assume that the errors are an innovation process, that is, we assume that the conditional mean of the errors is zero. We write the error process as: $\varepsilon_t = \sigma_t z_t$ where σ_t is the conditional standard deviation and the z terms are a sequence of independent, zero-mean, unit-variance, normally distributed variables. Under this assumption, the unconditional variance of the error process is the unconditional mean of the conditional variance. Note, however, that the unconditional variance of the process variable does not, in general, coincide with the unconditional variance of the error terms.

In financial and economic models, conditioning is often stated as regressions of the future values of the variables on the present and past values of the same variable. For example, if we assume that time is discrete, we can express conditioning as an autoregressive model:

$$X_{t+1} = \alpha_0 + \beta_0 X_t + \dots + \beta_n X_{t-n} + \varepsilon_{t+1}$$

The error term ε_i is conditional on the information I_i that, in this example, is represented by the present and the past n values of the variable X . The simplest autoregressive model is the random walk model of the logarithms of prices p_i :

$$p_{t+1} = \mu t + p_t + \varepsilon_t$$

In terms of returns, the random walk model is simply:

$$r_t = \Delta p_t = \mu + \varepsilon_t$$

A major breakthrough in econometric modeling was the discovery that, for many families of econometric models, linear and nonlinear alike, it is possible to specify a stochastic process for the error terms and predict the average size of the error terms when models are fitted to empirical data. This is the essence of ARCH modeling introduced by Engle (1982).

Two observations are in order. First, we have introduced two different types of heteroskedasticity. In the first example, regression errors are heteroskedastic because they depend on the value of the independent variables: The average error is larger when the independent variable is larger. In the second example, however, error terms are conditionally heteroskedastic because they vary with time and do not necessarily depend on the value of the process variables. Later in this entry we will describe a variant of the ARCH model where the size of volatility is correlated with the level of the variable. However, in the basic specification of ARCH models, the level of the variables and the size of volatility are independent.

Second, let's observe that the volatility (or the variance) of the error term is a hidden, nonobservable variable. Later in this entry, we will describe realized volatility models that treat volatility as an observed variable. Theoretically, however, time-varying volatility can be only inferred, not observed. As a consequence, the error term cannot be separated from the rest of the model. This occurs both because we have only one realization of the relevant time series and because the volatility term depends on the model used to forecast expected returns. The ARCH/GARCH behavior of the error term depends on the model chosen to represent the data. We might use different models to represent data with different levels of accuracy. Each model will be characterized by a different specification of heteroskedasticity.

Consider, for example, the following model for returns:

$$r_t = m + \varepsilon_t$$

In this simple model, the clustering of volatility is equivalent to the clustering of the squared returns (minus their constant mean). Now suppose that we discover that returns are predictable through a regression on some predictor f :

$$r_t = m + f_{t-1} + \varepsilon_t$$

As a result of our discovery, we can expect that the model will be more accurate, the size of the errors will decrease, and the heteroskedastic behavior will change.

Note that in the model $r_t = m + \varepsilon_t$, the errors coincide with the fluctuations of returns around their unconditional mean. If errors are an innovation process, that is, if the conditional mean of the errors is zero, then the variance of returns coincides with the variance of errors, and ARCH behavior describes the fluctuations of returns. However, if we were able to make conditional forecasts of returns, then the ARCH model describes the behavior of the errors and it is no longer true that the unconditional variance of errors coincides with the unconditional variance of returns. Thus, the statement that ARCH models describe the time evolution of the variance of returns is true only if returns have a constant expectation.

ARCH/GARCH effects are important because they are very general. It has been found empirically that most model families presently in use in econometrics and financial econometrics exhibit conditionally heteroskedastic errors when applied to empirical economic and financial data. The heteroskedasticity of errors has not disappeared with the adoption of more sophisticated models of financial variables. The ARCH/GARCH specification of errors allows one to estimate models more accurately and to forecast volatility.

ARCH/GARCH MODELS

In this section, we discuss univariate ARCH and GARCH models. Because in this entry we focus on financial applications, we will use finan-

cial notation. Let the dependent variable, which might be the return on an asset or a portfolio, be labeled r_t . The mean value m and the variance h will be defined relative to a past information set. Then the return r in the present will be equal to the conditional mean value of r (that is, the expected value of r based on past information) plus the conditional standard deviation of r (that is, the square root of the variance) times the error term for the present period:

$$r_t = m_t + \sqrt{h_t}z_t$$

The econometric challenge is to specify how the information is used to forecast the mean and variance of the return conditional on the past information. While many specifications have been considered for the mean return and used in efforts to forecast future returns, rather simple specifications have proven surprisingly successful in predicting conditional variances.

First, note that if the error terms were strict white noise (that is, zero-mean, independent variables with the same variance), the conditional variance of the error terms would be constant and equal to the unconditional variance of errors. We would be able to estimate the error variance with the empirical variance:

$$h = \frac{\sum_{i=1}^n \varepsilon_i^2}{n}$$

using the largest possible available sample. However, it was discovered that the residuals of most models used in financial econometrics exhibit a structure that includes heteroskedasticity and autocorrelation of their absolute values or of their squared values.

The simplest strategy to capture the time dependency of the variance is to use a short rolling window for estimates. In fact, before ARCH, the primary descriptive tool to capture time-varying conditional standard deviation and conditional variance was the rolling standard deviation or the rolling variance. This is the standard deviation or variance calculated using a fixed number of the most recent

observations. For example, a rolling standard deviation or variance could be calculated every day using the most recent month (22 business days) of data. It is convenient to think of this formulation as the first ARCH model; it assumes that the variance of tomorrow's return is an equally weighted average of the squared residuals of the last 22 days.

The idea behind the use of a rolling window is that the variance changes slowly over time, and it is therefore approximately constant on a short rolling-time window. However, given that the variance changes over time, the assumption of equal weights seems unattractive: It is reasonable to consider that more recent events are more relevant and should therefore have higher weights. The assumption of zero weights for observations more than one month old is also unappealing.

In the ARCH model proposed by Engle (1982), these weights are parameters to be estimated. Engle's ARCH model thereby allows the data to determine the best weights to use in forecasting the variance. In the original formulation of the ARCH model, the variance is forecasted as a moving average of past error terms:

$$h_t = \omega + \sum_{i=1}^p \alpha_i \varepsilon_{t-i}^2$$

where the coefficients α_i must be estimated from empirical data. The errors themselves will have the form

$$\varepsilon_t = \sqrt{h_t} z_t$$

where the z terms are independent, standard normal variables (that is, zero-mean, unit-variance, normal variables). In order to ensure that the variance is nonnegative, the constants (ω, α_i) must be nonnegative. If $\sum_{i=1}^p \alpha_i < 1$, the ARCH process is weakly stationary with constant unconditional variance:

$$\sigma^2 = \frac{\omega}{1 - \sum_{i=1}^p \alpha_i}$$

Two remarks should be made. First, ARCH is a forecasting model insofar as it forecasts the error variance at time t on the basis of information known at time $t - 1$. Second, forecasting is conditionally deterministic, that is, the ARCH model does not leave any uncertainty on the expectation of the squared error at time t knowing past errors. This must always be true of a forecast, but, of course, the squared error that occurs can deviate widely from this forecast value.

A useful generalization of this model is the GARCH parameterization introduced by Bollerslev (1986). This model is also a weighted average of past squared residuals, but it has declining weights that never go completely to zero. In its most general form, it is not a Markovian model, as all past errors contribute to forecast volatility. It gives parsimonious models that are easy to estimate and, even in its simplest form, has proven surprisingly successful in predicting conditional variances.

The most widely used GARCH specification asserts that the best predictor of the variance in the next period is a weighted average of the long-run average variance, the variance predicted for this period, and the new information in this period that is captured by the most recent squared residual. Such an updating rule is a simple description of adaptive or learning behavior and can be thought of as Bayesian updating. Consider the trader who knows that the long-run average daily standard deviation of the Standard and Poor's 500 is 1%, that the forecast he made yesterday was 2%, and the unexpected return observed today is 3%. Obviously, this is a high-volatility period, and today is especially volatile, suggesting that the volatility forecast for tomorrow could be even higher. However, the fact that the long-term average is only 1% might lead the forecaster to lower his forecast. The best strategy depends on the dependence between days. If these three numbers are each squared and weighted equally, then the new forecast would be $2.16 = \sqrt{(1 + 4 + 9)}/3$. However, rather than weighting these equally, for daily data it is

generally found that weights such as those in the empirical example of (0.02, 0.9, 0.08) are much more accurate. Hence, the forecast is $2.08 = \sqrt{0.02 \times 1 + 0.9 \times 4 + 0.08 \times 9}$. To be precise, we can use h_t to define the variance of the residuals of a regression $r_t = m_t + \sqrt{h_t}\varepsilon_t$. In this definition, the variance of ε_t is one. Therefore, a GARCH(1,1) model for variance looks like this:

$$h_{t+1} = \omega + \alpha (r_t - m_t)^2 + \beta h_t = \omega + \alpha h_t \varepsilon_t^2 + \beta h_t$$

This model forecasts the variance of date t return as a weighted average of a constant, yesterday's forecast, and yesterday's squared error. If we apply the previous formula recursively, we obtain an infinite weighted moving average. Note that the weighting coefficients are different from those of a standard exponentially weighted moving average (EWMA). The econometrician must estimate the constants ω, α, β ; updating simply requires knowing the previous forecast h and the residual.

The weights are $(1 - \alpha - \beta, \beta, \alpha)$ and the long-run average variance is $\sqrt{\omega / (1 - \alpha - \beta)}$. It should be noted that this works only if $\alpha + \beta < 1$ and it really makes sense only if the weights are positive, requiring $\alpha > 0, \beta > 0, \omega > 0$. In fact, the GARCH(1,1) process is weakly stationary if $\alpha + \beta < 1$. If $E[\log(\beta + \alpha z^2)] < 0$, the process is strictly stationary. The GARCH model with $\alpha + \beta = 1$ is called an *integrated GARCH* or IGARCH. It is a strictly stationary process with infinite variance.

The GARCH model described above and typically referred to as the GARCH(1,1) model derives its name from the fact that the 1,1 in parentheses is a standard notation in which the first number refers to the number of autoregressive lags (or ARCH terms) that appear in the equation and the second number refers to the number of moving average lags specified (often called the number of GARCH terms). Models with more than one lag are sometimes needed to find good variance forecasts. Although this model is directly set up to forecast for just one

period, it turns out that, based on the one-period forecast, a two-period forecast can be made. Ultimately, by repeating this step, long-horizon forecasts can be constructed. For the GARCH(1,1), the two-step forecast is a little closer to the long-run average variance than is the one-step forecast, and, ultimately, the distant-horizon forecast is the same for all time periods as long as $\alpha + \beta < 1$. This is just the unconditional variance. Thus, GARCH models are mean reverting and conditionally heteroskedastic but have a constant unconditional variance.

Let's now address the question of how the econometrician can estimate an equation like the GARCH(1,1) when the only variable on which there are data is r_t . One possibility is to use maximum likelihood by substituting h_t for σ^2 in the normal likelihood and then maximizing with respect to the parameters. GARCH estimation is implemented in commercially available software such as EViews, GAUSS, Matlab, RATS, SAS, or TSP. The process is quite straightforward: For any set of parameters ω, α, β and a starting estimate for the variance of the first observation, which is often taken to be the observed variance of the residuals, it is easy to calculate the variance forecast for the second observation. The GARCH updating formula takes the weighted average of the unconditional variance, the squared residual for the first observation, and the starting variance and estimates the variance of the second observation. This is input into the forecast of the third variance, and so forth. Eventually, an entire time series of variance forecasts is constructed.

Ideally, this series is large when the residuals are large and small when the residuals are small. The likelihood function provides a systematic way to adjust the parameters ω, α, β to give the best fit. Of course, it is possible that the true variance process is different from the one specified by the econometrician. In order to check this, a variety of diagnostic tests are available. The simplest is to construct the series of $\{\varepsilon_t\}$, which are supposed to have constant mean

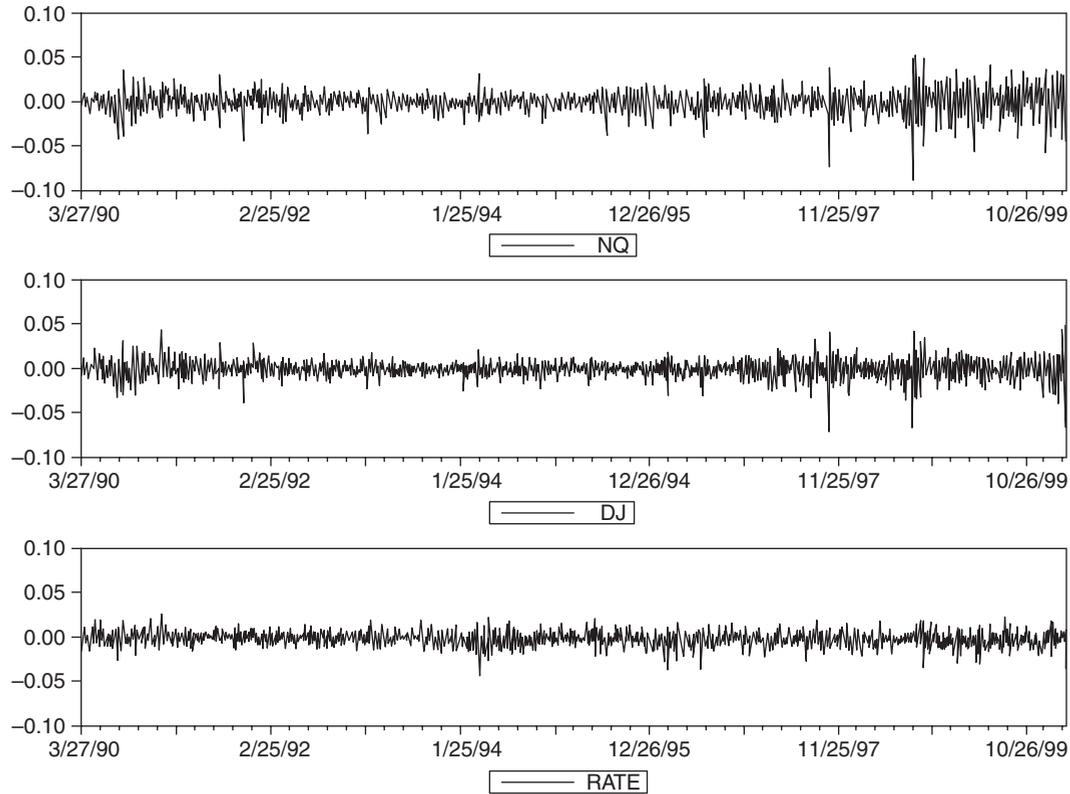

Figure 1 Nasdaq, Dow Jones, and Bond Returns

and variance if the model is correctly specified. Various tests, such as tests for autocorrelation in the squares, can detect model failures. The Ljung-Box test with 15 lagged autocorrelations is often used.

Application to Value at Risk

Applications of the ARCH/GARCH approach are widespread in situations where the volatility of returns is a central issue. Many banks and other financial institutions use the idea of *value at risk* (VaR) as a way to measure the risks in their portfolios. The 1% VaR is defined as the number of dollars that one can be 99% certain exceeds any losses for the next day. Let's use the GARCH(1,1) tools to estimate the 1% VaR of a \$1 million portfolio on March 23, 2000. This portfolio consists of 50% Nasdaq, 30% Dow

Jones, and 20% long bonds. We chose this date because, with the fall of equity markets in the spring of 2000, it was a period of high volatility. First, we construct the hypothetical historical portfolio. (All calculations in this example were done with the EViews software program.) Figure 1 shows the pattern of the Nasdaq, Dow Jones, and long Treasury bonds. In Table 1, we present some illustrative statistics for each of these three investments separately and, in

Table 1 Portfolio Data

	NQ	DJ	RATE	PORT
Mean	0.0009	0.0005	0.0001	0.0007
Std. Dev.	0.0115	0.0090	0.0073	0.0083
Skewness	-0.5310	-0.3593	-0.2031	-0.4738
Kurtosis	7.4936	8.3288	4.9579	7.0026

Table 2 GARCH(1,1)

Dependent Variable: PORT				
Sample (adjusted): 3/26/1990 3/23/2000				
Convergence achieved after 16 iterations				
Bollerslev-Wooldrige robust standard errors and covariance				
Variance Equation				
C	0.0000	0.0000	3.1210	0.0018
ARCH(1)	0.0772	0.0179	4.3046	0.0000
GARCH(1)	0.9046	0.0196	46.1474	0.0000
S.E. of regression	0.0083	Akaike info criterion		-6.9186
Sum squared resid	0.1791	Schwarz criterion		-6.9118
Log likelihood	9028.2809	Durbin-Watson stat		1.8413

the final column, for the portfolio as a whole. Then we forecast the standard deviation of the portfolio and its 1% quantile. We carry out this calculation over several different time frames: the entire 10 years of the sample up to March 23, 2000, the year before March 23, 2000, and from January 1, 2000 to March 23, 2000.

Consider first the quantiles of the historical portfolio at these three different time horizons. Over the full 10-year sample, the 1% quantile times \$1 million produces a VaR of \$22,477. Over the last year, the calculation produces a VaR of \$24,653—somewhat higher, but not significantly so. However, if the first quantile is calculated based on the data from January 1, 2000, to March 23, 2000, the VaR is \$35,159. Thus, the level of risk has increased significantly over the last quarter.

The basic GARCH(1,1) results are given in Table 2. Notice that the coefficients sum up to a number slightly less than one. The forecasted standard deviation for the next day is 0.014605, which is almost double the average standard deviation of 0.0083 presented in the last column of Table 1. If the residuals were normally distributed, then this would be multiplied by 2.326348, giving a VaR equal to \$33,977. As it turns out, the standardized residuals, which are the estimated values of $\{\varepsilon_t\}$, have a 1% quantile of 2.8437, which is well above the normal quantile. The estimated 1% VaR is \$39,996. Notice that this VaR has risen to reflect the increased risk in 2000.

Finally, the VaR can be computed based solely on estimation of the quantile of the forecast distribution. This has been proposed by Engle and Manganelli (2001), adapting the quantile regression methods of Koenker and Basset (1978). Application of their method to this dataset delivers a VaR of \$38,228. Instead of assuming the distribution of return series, Engle and Manganelli (2004) propose a new VaR modeling approach, *conditional autoregressive value at risk (CAViaR)*, to directly compute the quantile of an individual financial asset. On a theoretical level, due to structural changes of the return series, the constant-parameter CAViaR model can be extended. Huang et al. (2010) formulate a time-varying CAViaR model, which they call an index-exciting time-varying CAViaR model. The model incorporates the market index information to deal with the unobservable structural break points for the individual risky asset.

WHY ARCH/GARCH?

The ARCH/GARCH framework proved to be very successful in predicting volatility changes. Empirically, a wide range of financial and economic phenomena exhibit the clustering of volatilities. As we have seen, ARCH/GARCH models describe the time evolution of the average size of squared errors, that is, the evolution of the magnitude of uncertainty. Despite the empirical success of ARCH/GARCH models, there is no real consensus on the economic

reasons why uncertainty tends to cluster. That is why models tend to perform better in some periods and worse in other periods.

It is relatively easy to induce ARCH behavior in simulated systems by making appropriate assumptions on agent behavior. For example, one can reproduce ARCH behavior in artificial markets with simple assumptions on agent decision-making processes. The real economic challenge, however, is to explain ARCH/GARCH behavior in terms of features of agents behavior and/or economic variables that could be empirically ascertained.

In classical physics, the amount of uncertainty inherent in models and predictions can be made arbitrarily low by increasing the precision of initial data. This view, however, has been challenged in at least two ways. First, quantum mechanics has introduced the notion that there is a fundamental uncertainty in any measurement process. The amount of uncertainty is prescribed by the theory at a fundamental level. Second, the theory of complex systems has shown that nonlinear complex systems are so sensitive to changes in initial conditions that, in practice, there are limits to the accuracy of any model. ARCH/GARCH models describe the time evolution of uncertainty in a complex system.

In financial and economic models, the future is always uncertain but over time we learn new information that helps us forecast this future. As asset prices reflect our best forecasts of the future profitability of companies and countries, these change whenever there is news. ARCH/GARCH models can be interpreted as measuring the intensity of the news process. Volatility clustering is most easily understood as news clustering. Of course, many things influence the arrival process of news and its impact on prices. Trades convey news to the market and the macroeconomy can moderate the importance of the news. These can all be thought of as important determinants of the volatility that is picked up by ARCH/GARCH.

GENERALIZATIONS OF THE ARCH/GARCH MODELS

Thus far, we have described the fundamental ARCH and GARCH models and their application to VaR calculations. The ARCH/GARCH framework proved to be a rich framework and many different extensions and generalizations of the initial ARCH/GARCH models have been proposed. We will now describe some of these generalizations and extensions. We will focus on applications in finance and will continue to use financial notation assuming that our variables represent returns of assets or of portfolios.

Let's first discuss why we need to generalize the ARCH/GARCH models. There are three major extensions and generalizations:

1. Integration of first, second, and higher moments
2. Generalization to high-frequency data
3. Multivariate extensions

Integration of First, Second, and Higher Moments

In the ARCH/GARCH models considered thus far, returns are assumed to be normally distributed and the forecasts of the first and second moments independent. These assumptions can be generalized in different ways, either allowing the conditional distribution of the error terms to be non-normal and/or integrating the first and second moments.

Let's first consider asymmetries in volatility forecasts. There is convincing evidence that the direction does affect volatility. Particularly for broad-based equity indexes and bond market indexes, it appears that market declines forecast higher volatility than do comparable market increases. There are now a variety of asymmetric GARCH models, including the *exponential GARCH (EGARCH)* model of Nelson (1991), the *threshold ARCH (TARCH)* model attributed to Rabemananjara and Zakoian (1993) and Glosten, Jagannathan, and Runkle (1993),

and a collection and comparison by Engle and Ng (1993).

In order to illustrate asymmetric GARCH, consider, for example, the asymmetric GARCH(1,1) model of Glosten, Jagannathan, and Runkle (1993). In this model, we add a term $\gamma (I_{\{\varepsilon_t < 0\}}) \varepsilon_t^2$ to the basic GARCH:

$$h_{t+1} = \omega + \alpha h_t \varepsilon_t^2 + \gamma (I_{\{\varepsilon_t < 0\}}) \varepsilon_t^2 + \beta h_t.$$

The term $(I_{\{\varepsilon_t < 0\}})$ is an indicator function that is zero when the error is positive and 1 when it is negative. If γ is positive, negative errors are leveraged. The parameters of the model are assumed to be positive. The relationship $\alpha + \beta + \gamma/2 < 1$ is assumed to hold.

In addition to asymmetries, it has been empirically found that residuals of ARCH/GARCH models fitted to empirical financial data exhibit excess kurtosis. One way to handle this problem is to consider non-normal distributions of errors. Non-normal distributions of errors were considered by Bollerslev (1987), who introduced a GARCH model where the variable z follows a Student- t distribution.

Let's now discuss the integration of first and second moments through the *GARCH-M* model. ARCH/GARCH models imply that the risk inherent in financial markets varies over time. Given that financial markets implement a risk-return trade-off, it is reasonable to ask whether changing risk entails changing returns. Note that, in principle, predictability of returns in function of predictability of risk is not a violation of market efficiency. To correlate changes in volatility with changes in returns, Engle, Lilien, and Robins (1987) proposed the GARCH-M model (not to be confused with the multivariate *MGARCH* model that will be described shortly). The GARCH-M model, or GARCH in mean model, is a complete nonlinear model of asset returns and not only a specification of the error behavior. In the GARCH-M model, returns are assumed to be a constant plus a term proportional to the conditional variance:

$$r_{t+1} = \mu_t + \sigma_t z_t, \quad \mu_t = \mu_0 + \mu_1 \sigma_t^2$$

where σ_t^2 follows a GARCH process and the z terms are independent and identically distributed (IID) normal variables. Alternatively, the GARCH-M process can be specified making the mean linear in the standard deviation but not in the variance.

The integration of volatilities and expected returns, that is the integration of risk and returns, is a difficult task. The reason is that not only volatilities but also correlations should play a role. The GARCH-M model was extended by Bollerslev (1986) in a multivariate context. The key challenge of these extensions is the explosion in the number of parameters to estimate; we will see this when discussing multivariate extensions in the following sections.

Generalizations to High-Frequency Data

With the advent of electronic trading, a growing amount of data has become available to practitioners and researchers. In many markets, data at transaction level, called tick-by-tick data or *ultra-high-frequency data*, are now available. The increase of data points in moving from daily data to transaction data is significant. For example, the average number of daily transactions for U.S. stocks in the Russell 1000 is in the order of 2,000. Thus, we have a 2,000-fold increase in data going from daily data to tick-by-tick data.

The interest in high-frequency data is twofold. First, researchers and practitioners want to find events of interest. For example, the measurement of intraday risk and the discovery of trading profit opportunities at short time horizons are of interest to many financial institutions. Second, researchers and practitioners would like to exploit high-frequency data to obtain more precise forecasts at the usual forecasting horizon. Let's focus on the latter objective.

As observed by Merton (1980), while in diffusive processes the estimation of trends requires long stretches of data, the estimation of volatility can be done with arbitrary precision using data extracted from arbitrarily short time

periods provided that the sampling rate is arbitrarily high. In other words, in diffusive models, the estimation of volatility greatly profits from high-frequency data. It therefore seems tempting to use data at the highest possible frequency, for example spaced at a few minutes, to obtain better estimates of volatility at the frequency of practical interest, say daily or weekly. As we will see, the question is not so straightforward and the answer is still being researched.

We will now give a brief account of the main modeling strategies and the main obstacles in using high-frequency data for volatility estimates. We will first assume that the return series are sampled at a high but fixed frequency. In other words, we initially assume that data are taken at fixed intervals of time. Later, we will drop this assumption and consider irregularly spaced tick-by-tick data, what Engle (2000) refers to as “ultra-high-frequency data.”

Let's begin by reviewing some facts about the *temporal aggregation* of models. The question of temporal aggregation is the question of whether models maintain the same form when used at different time scales. This question has two sides: empirical and theoretical. From the empirical point of view, it is far from being obvious that econometric models maintain the same form under temporal aggregation. In fact, patterns found at some time scales might disappear at another time scale. For example, at very short time horizons, returns exhibit autocorrelations that disappear at longer time horizons. Note that it is not a question of the precision and accuracy of models. Given the uncertainty associated with financial modeling, there are phenomena that exist at some time horizon and disappear at other time horizons.

Time aggregation can also be explored from a purely theoretical point of view. Suppose that a time series is characterized by a given data-generating process (DGP). We want to investigate what DGPs are closed under temporal aggregation; that is, we want to investigate

what DGPs, eventually with different parameters, can represent the same series sampled at different time intervals.

The question of time aggregation for GARCH processes was explored by Drost and Nijman (1993). Consider an infinite series $\{x_t\}$ with given fixed-time intervals $\Delta x_t = x_{t+1} - x_t$. Suppose that the series $\{x_t\}$ follows a GARCH(p, q) process. Suppose also that we sample this series at intervals that are multiples of the basic intervals: $\Delta y_t = h \Delta x_t = x_{t+h} - x_t$. We obtain a new series $\{y_t\}$. Drost and Nijman found that the new series $\{y_t\}$ does not, in general, follow another GARCH(p', q') process. The reason is that, in the standard GARCH definition presented in the previous sections, the series $\{x_t = \sigma_t z_t\}$ is supposed to be a martingale difference sequence (that is, a process with zero conditional mean). This property is not conserved at longer time horizons.

To solve this problem, Drost and Nijman introduced weak GARCH processes, processes that do not assume the martingale difference condition. They were able to show that weak GARCH(p, q) models are closed under temporal aggregation and established the formulas to obtain the parameters of the new process after aggregation. One consequence of their formulas is that the fluctuations of volatility tend to disappear when the time interval becomes very large. This conclusion is quite intuitive given that conditional volatility is a mean-reverting process.

Christoffersen, Diebold, and Schuerman (1998) use the Drost and Nijman formula to show that the usual scaling of volatility, which assumes that volatility scales with the square root of time as in the random walk, can be seriously misleading. In fact, the usual scaling magnifies the GARCH effects when the time horizon increases while the Drost and Nijman analysis shows that the GARCH effect tends to disappear with growing time horizons. If, for example, we fit a GARCH model to daily returns and then scale to monthly volatility multiplying by the square root of the number of days in

a month, we obtain a seriously biased estimate of monthly volatility.

Various proposals to exploit high-frequency data to estimate volatility have been made. Meddahi and Renault (2004) proposed a class of autoregressive stochastic volatility models—the SR-SARV model class—that are closed under temporal aggregation; they thereby avoid the limitations of the weak GARCH models. Andersen and Bollerslev (1998) proposed realized volatility as a virtually error-free measure of instantaneous volatility. To compute realized volatility using their model, one simply sums intraperiod high-frequency squared returns.

Thus far, we have briefly described models based on regularly spaced data. However, the ultimate objective in financial modeling is using all the available information. The maximum possible level of information on returns is contained in tick-by-tick data. Engle and Russell (1998) proposed the *autoregressive conditional duration* (ACD) model to represent sequences of random times subject to clustering phenomena. In particular, the ACD model can be used to represent the random arrival of orders or the random time of trade execution.

The arrival of orders and the execution of trades are subject to clustering phenomena insofar as there are periods of intense trading activity with frequent trading followed by periods of calm. The ACD model is a point process. The simplest point process is likely the Poisson process, where the time between point events is distributed as an exponential variable independent of the past distribution of points. The ACD model is more complex than a Poisson process because it includes an autoregressive effect that induces the point process equivalent of ARCH effects. As it turns out, the ACD model can be estimated using standard ARCH/GARCH software. Different extensions of the ACD model have been proposed. In particular, Bauwens and Giot (1997) introduced the logarithmic ACD model to represent the bid-ask prices in the Nasdaq stock market.

Ghysel and Jasiak (1997) introduced a class of approximate ARCH models of returns series sampled at the time of trade arrivals. This model class, called *ACD-GARCH*, uses the ACD model to represent the arrival times of trades. The GARCH parameters are set as a function of the duration between transactions using insight from the Drost and Nijman weak GARCH. The model is bivariate and can be regarded as a random coefficient GARCH model.

Multivariate Extensions

The models described thus far are models of single assets. However, in finance, we are also interested in the behavior of portfolios of assets. If we want to forecast the returns of portfolios of assets, we need to estimate the correlations and covariances between individual assets. We are interested in modeling correlations not only to forecast the returns of portfolios but also to respond to important theoretical questions. For example, we are interested in understanding if there is a link between the magnitude of correlations and the magnitude of variances and how correlations propagate between different markets. Questions like these have an important bearing on investment and risk management strategies.

Conceptually, we can address covariances in the same way as we addressed variances. Consider a vector of N return processes: $r_t = \{r_{i,t}\}$, $i = 1, \dots, N$, $t = 1, \dots, T$. At every moment t , the vector r_t can be represented as: $r_t = m_t(\vartheta) + \varepsilon_t$, where $m_t(\vartheta)$ is the vector of conditional means that depend on a finite vector of parameters ϑ and the term ε_t is written as:

$$\varepsilon_t = H_t^{1/2}(\vartheta) z_t$$

where $H_t^{1/2}(\vartheta)$ is a positive definite matrix that depends on the finite vector of parameters ϑ . We also assume that the N -vector z_t has the following moments: $E(z_t) = 0$, $\text{Var}(z_t) = I_N$ where I_N is the $N \times N$ identity matrix.

To explain the nature of the matrix $H_t^{1/2}(\vartheta)$, consider that we can write:

$$\begin{aligned}\text{Var}(r_t|I_{t-1}) &= \text{Var}_{t-1}(r_t) = \text{Var}_{t-1}(\varepsilon_t) \\ &= H_t^{1/2} \text{Var}_{t-1}(z_t) H_t^{1/2'} = H_t\end{aligned}$$

where I_{t-1} is the information set at time $t - 1$. For simplicity, we left out in the notation the dependence on the parameters ϑ . Thus $H_t^{1/2}$ is any positive definite $N \times N$ matrix such that H_t is the conditional covariance matrix of the process r_t . The matrix $H_t^{1/2}$ could be obtained by Cholesky factorization of H_t . Note the formal analogy with the definition of the univariate process.

Consider that both the vector $m_t(\vartheta)$ and the matrix $H_t^{1/2}(\vartheta)$ depend on the vector of parameters ϑ . If the vector ϑ can be partitioned into two subvectors, one for the mean and one for the variance, then the mean and the variance are independent. Otherwise, there will be an integration of mean and variance as was the case in the univariate GARCH-M model. Let's abstract from the mean, which we assume can be modeled through some autoregressive process, and focus on the process $\varepsilon_t = H_t^{1/2}(\vartheta) z_t$.

We will now define a number of specifications for the variance matrix H_t . In principle, we might consider the covariance matrix heteroskedastic and simply extend the ARCH/GARCH modeling to the entire covariance matrix. There are three major challenges in MGARCH models:

1. Determining the conditions that ensure that the matrix H_t is positive definite for every t .
2. Making estimates feasible by reducing the number of parameters to be estimated.
3. Stating conditions for the weak stationarity of the process.

In a multivariate setting, the number of parameters involved makes the (conditional) covariance matrix very noisy and virtually impossible to estimate without appropriate restrictions. Consider, for example, a large aggregate such as the S&P 500. Due to symme-

tries, there are approximately 125,000 entries in the conditional covariance matrix of the S&P 500. If we consider each entry as a separate GARCH(1,1) process, we would need to estimate a minimum of three GARCH parameters per entry. Suppose we use three years of data for estimation, that is, approximately 750 data points for each stock's daily returns. In total, there are then $500 \times 750 = 375,000$ data points to estimate $3 \times 125,000 = 375,000$ parameters. Clearly, data are insufficient and estimation is therefore very noisy. To solve this problem, the number of independent entries in the covariance matrix has to be reduced.

Consider that the problem of estimating large covariance matrices is already severe if we want to estimate the unconditional covariance matrix of returns. Using the theory of random matrices, Potter, Bouchaud, Laloux, and Cizeau (1999) show that only a small number of the eigenvalues of the covariance matrix of a large aggregate carry information, while the vast majority of the eigenvalues cannot be distinguished from the eigenvalues of a random matrix. Techniques that impose constraints on the matrix entries, such as factor analysis or principal components analysis, are typically employed to make less noisy the estimation of large covariance matrices.

Assuming that the conditional covariance matrix is time varying, the simplest estimation technique is using a rolling window. Estimating the covariance matrix on a rolling window suffers from the same problems already discussed in the univariate case. Nevertheless, it is one of the two methods used in RiskMetrics. The second method is the EWMA method. EWMA estimates the covariance matrix using the following equation:

$$H_t = \alpha \varepsilon_t \varepsilon_t' + (1 - \alpha) H_{t-1}$$

where α is a small constant.

Let's now turn to multivariate GARCH specifications, or MGARCH, and begin by introducing the vech notation. The vech operator stacks the lower triangular portion of an $N \times N$ matrix

as an $N(N+1)/2 \times 1$ vector. In the vech notation, the MGARCH(1,1) model, called the VEC model, is written as follows:

$$h_t = \omega + A\eta_{t-1} + Bh_{t-1}$$

where $h_t = \text{vech}(H_t)$, ω is an $N(N+1)/2 \times 1$ vector, and A, B are $N(N+1)/2 \times N(N+1)/2$ matrices.

The number of parameters in this model makes its estimation impossible except in the bivariate case. In fact, for $N = 3$ we should already estimate 78 parameters. In order to reduce the number of parameters, Bollerslev, Engle, and Wooldridge (1988) proposed the diagonal VEC model (DVEC), imposing the restriction that the matrices A, B be diagonal matrices. In the DVEC model, each entry of the covariance matrix is treated as an individual GARCH process. Conditions to ensure that the covariance matrix H_t is positive definite are derived in Attanasio (1991). The number of parameters of the DVEC model, though much smaller than the number of parameters in the full VEC formulation, is still very high: $3N(N+1)/2$.

To simplify conditions to ensure that H_t is positive definite, Engle and Kroner (1995) proposed the BEKK model (the acronym BEKK stands for Baba, Engle, Kraft, and Kroner). In its most general formulation, the BEKK(1,1,K) model is written as follows:

$$H_t = CC' + \sum_{k=1}^K A'_k \varepsilon_{t-1} \varepsilon'_{t-1} A_k + \sum_{k=1}^K B'_k H_{t-1} B_k$$

where C, A_k, B_k are $N \times N$ matrices and C is upper triangular. The BEKK(1,1,1) model simplifies as follows:

$$H_t = CC' + A' \varepsilon_{t-1} \varepsilon'_{t-1} A + B' H_{t-1} B$$

which is a multivariate equivalent of the GARCH(1,1) model. The number of parameters in this model is very large; the diagonal BEKK was proposed to reduce the number of parameters.

The VEC model can be weakly (covariance) stationary but exhibit a time-varying conditional covariance matrix. The stationarity con-

ditions require that the eigenvalues of the matrix $A + B$ are less than one in modulus. Similar conditions can be established for the BEKK model. The unconditional covariance matrix H is the unconditional expectation of the conditional covariance matrix. We can write:

$$H = [I_{N^*} - A - B]^{-1}, \quad N^* = N(N+1)/2 \times$$

MGARCH based on factor models offers a different modeling strategy. Standard (strict) factor models represent returns as linear regressions on a small number of common variables called factors:

$$r_t = m + Bf_t + \varepsilon_t$$

where r_t is a vector of returns, f_t is a vector of K factors, B is a matrix of factor loadings, ε_t is noise with diagonal covariance, so that the covariance between returns is accounted for only by the covariance between the factors. In this formulation, factors are static factors without a specific time dependence. The unconditional covariance matrix of returns Ω can be written as:

$$\Omega = B\Omega_K B' + \Sigma$$

where Ω_K is the covariance matrix of the factors.

We can introduce a dynamics in the expectations of returns of factor models by making some or all of the factors dynamic, for example, assuming an autoregressive relationship:

$$\begin{aligned} r_t &= m + Bf_t + \varepsilon_t \\ f_{t+1} &= a + bf_t + \eta_t \end{aligned}$$

We can also introduce a dynamic of volatilities assuming a GARCH structure for factors. Engle, Ng, and Rothschild (1990) used the notion of *factors* in a dynamic conditional covariance context assuming that one factor, the market factor, is *dynamic*. Various GARCH factor models have been proposed: the *F-GARCH* model of Lin (1992); the full factor FF-GARCH model of Vrontos, Dellaportas, and Politis (2003); the orthogonal O-GARCH model of Kariya (1988); and Alexander and Chibumba (1997).

Another strategy is followed by Bollerslev (1990) who proposed a class of GARCH models in which the conditional correlations are constant and only the idiosyncratic variances are time varying (CCC model). Engle (2002) proposed a generalization of Bollerslev's CCC model called the dynamic conditional correlation (DCC) model.

KEY POINTS

- Volatility, a key parameter used in many financial applications, measures the size of the errors made in modeling returns and other financial variables. For vast classes of models, the average size of volatility is not constant but changes with time and is predictable.
- In standard regression theory, the assumption of homoskedasticity is convenient from a mathematical point of view. The homoskedasticity assumption means that the expected size of the error is constant and does not depend on the size of the explanatory variable. When it is assumed in regression analysis that the expected size of the error term is not constant, this means the error terms are assumed to be heteroskedastic.
- A major breakthrough in econometric modeling was the discovery that for many families of econometric models it is possible to specify a stochastic process for the error terms and predict the average size of the error terms when models are fitted to empirical data. This is the essence of ARCH modeling. This original modeling of conditional heteroskedasticity has developed into a full-fledged econometric theory of the time behavior of the errors of a large class of univariate and multivariate models.
- The availability of more and better data and the availability of low-cost, high-performance computers allowed the development of a vast family of ARCH/GARCH models. Among these are the EGARCH, IGARCH, GARCH-M, MGARCH, and ACD models.
- While the forecasting of expected returns remains a rather elusive task, predicting the level of uncertainty and the strength of comovements between asset returns has become a fundamental pillar of financial econometrics.

Abstract: Classification and regression trees (CART) are nonparametric and nonlinear modeling techniques that do not rely upon the many stringent assumptions required by classical parametric models. Despite the fact that researchers in many fields have regularly found trees to be an attractive way to express underlying relationships, they are relatively unfamiliar to financial modelers where the historical focus of financial modeling has been on parametric regression. Although the linear type of regression analysis is convenient and sometimes intuitive, it may not fully capture the complexity of financial markets. As the quantity and variety of financial information available to data exploration have increased over time, there has been a commensurate need for a more robust and versatile process to analyze these data. CART offers a valuable alternative to traditional methods for modeling financial data.

Classification and regression trees (CART) are nonparametric and nonlinear modeling techniques that essentially use recursive partitioning techniques to separate observations in a binary and sequential fashion. There are two varieties: (1) classification trees when the dependent variable is categorical, and (2) regression trees when the dependent variable is continuous.

Although the approach is not widely utilized within the investment community, the applications of CART to financial markets

nevertheless include the classification of financially distressed firms by Frydman, Altman, and Kao (1985), asset allocation by Sorensen, Mezrich, and Miller (1998), equity style timing by Kao and Shumaker (1999), and stock selection by Sorensen, Miller, and Ooi (2000). In this entry we provide an introduction to the CART framework and contrast it to more traditional modeling methods. We then illustrate the technique by applying it to stock selection across the North American equity markets.

TECHNICAL DETAILS

We begin by introducing the standard tree terminology. The root is the top node, which includes all observations in the learning sample. The splitting condition at each node is expressed as an “if-then-else” rule that is determined by a specific splitting criterion. The splitting node is also called the parent and the two descendant subnodes are called children. A node keeps splitting until a terminal node or leaf is reached.

The fundamental idea behind CART is to recursively partition the space until all the subspaces are sufficiently homogenous in order to apply simple models to them. This is in contrast to linear and logistic regressions, the linear parametric counterparts of regression and classification trees, respectively, which are global models where a single predictive formula is imposed over the entire data space. When the dataset has multiple features that interact in complicated and nonlinear ways, as is often the case with financial data, a single global model may inadequately capture the underlying relationships.

There are two major steps in the CART analysis: (1) Build a tree using a recursive splitting of nodes, and (2) prune the tree in order to obtain the optimal tree size so as to prevent overfitting. Each of these two steps will be discussed in more detail below. Breiman et al. (1984) provide a detailed overview of the theory and methodology of CART, including a number of examples from many disciplinary areas. There are also many software packages that implement the CART algorithm. Popular ones include R packages such as *rpart* and *tree* and the Matlab function *classregtree*.

Binary Recursive Partitioning

Let \mathcal{L} be a learning sample, $\mathcal{L} = \{(x_1, y_1), \dots, (x_n, y_n)\}$, where x_i is a vector of attributes; y_i is the response, which can be categorical or continuous; and n is the number of observations. The attribute vector x_i belongs to X , the

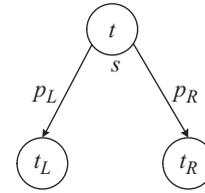

Figure 1 A split generates two children of the node t , denoted by t_L and t_R . A proportion p_L of the initial data go into the left child and a proportion of p_R go into the right child.

attribute space. The tree-building algorithm involves repeatedly splitting subsets of \mathcal{L} into two descendant subsets, beginning with \mathcal{L} itself. For a continuous variable x_i , the allowed splits are of the form $x_i < c$ versus $x_i \geq c$. For categorical variables the levels are divided into two classes. Therefore, for a categorical variable with K levels, there are $2^{K-1} - 1$ possible splits, disallowing the empty split and ignoring the order.

In choosing the best splitting rule, CART seeks to maximize the average purity of the two child nodes. Hence, some criterion measuring data homogeneity or, alternatively, impurity should be introduced. These impurity measures are loosely classed splitting criteria. Let us introduce, for any node t , a measure $i(t)$ that signifies the impurity of the node. Suppose that a candidate split s divides the node into t_L and t_R such that a proportion p_L of the cases in t go into t_L and a proportion p_R go into t_R (see Figure 1). Then the goodness of the split is defined to be the decrease of impurity

$$\Delta i(s, t) = i(t) - p_L i(t_L) - p_R i(t_R)$$

For an arbitrary node t and a set of splitting candidates S , the optimal split is chosen to be the one

$$s^* = \max_{s \in S} \Delta i(s, t)$$

In other words, the optimal split is the one that reduces impurity by the greatest amount.

The idea for classification and regression trees is quite similar in terms of partitioning methods, which is based on impurity reducing.

However, they use different measures of impurity to decode the split.

In a classification problem, suppose that we want to classify data into K classes. At each node t of a classification tree we have a probability distribution p_{tk} , $k = 1, \dots, K$, over all K categories. The probabilities are conventionally estimated from the node proportions, such that $p_{tk} = n_{tk}/n_t$, where n_{tk} is the number of observations in the k -th class, and n_t is the sample size at node t .

The two most common measures of impurity are the Gini index

$$i(t) = \sum_{j \neq k} p_{tj} p_{tk} = 1 - \sum_k p_{tk}^2$$

and entropy or information

$$i(t) = - \sum_k p_{tk} \log(p_{tk})$$

where $0 \log(0) = 0$.

As for regression trees, the most popular impurity measure is

$$i(t) = \sum_{j=1}^{n_t} (y_{tj} - \mu_t)^2$$

where the constant μ_t for node t is estimated by the mean of the values of the training data falling into node t .

TREE PRUNING

However, the use of partitioning rules alone cannot guarantee a useful tree model. If reducing impurity is the only goal in tree induction, we will eventually end up with a maximal tree, which has one observation or one class in each leaf, whichever reaches first. This kind of tree adapts too well to the features of the learning sample and has a very high risk of being overfitted. Tree pruning is a way to improve the robustness of the model by trading off in-sample fitting against out-of-sample accuracy. This is particularly important if the model is being used to make predictions.

The best-known procedure for tree pruning is the cost-complexity pruning proposed by Breiman et al. (1984). Let T be a subtree of the maximal tree grown without pruning. Let the

size of a tree be the number of terminal nodes. The optimal tree is the one that minimizes the following cost-complexity measure

$$R_\alpha(T) = R(T) + \alpha \text{size}(T)$$

where α is a complexity parameter to penalize the tree size, and R is the cost, which is commonly taken as misclassification errors in classification cases and deviance in regression cases. For a given value of the complexity parameter α , an optimal tree can be determined. In general, finding the optimal value for α would require an independent set of data (i.e., a testing sample). This requirement is often avoided in practice by using a cross validation procedure.

STRENGTHS AND WEAKNESSES OF CART

Compared to classical parametric models, CART offers a number of benefits in data exploration. In particular, it has a very high degree of interpretability. CART efficiently compresses a large volume of data into an easy-to-understand graphical form that identifies the essential characteristics. It is also very flexible in terms of the structure of the input variables, as either categorical or continuous factors or a combination can be used as inputs. Furthermore, CART is quite robust in the presence of outliers and well suited to noisy datasets, both of which tend to be features of financial data.

Being nonparametric it does not require any assumptions to be made about the underlying distribution of the variables being modeled. The high incidences of extreme events in the financial markets suggest that the supposition of distributional normality is questionable in many areas of finance. While the assumption may in many cases be a fair approximation to the underlying structural relationship, it is quite rare that tests for non-normality or nonlinearity are explicitly assessed in advance even though this information would help to inform the appropriate choice of modeling technique.

The CART approach also departs from traditional modeling methods by determining a hierarchy of input variables that may be closer to the human decision-making processes. Indeed, a key strength of CART over classical modeling methods is that it allows one to represent various types of *interactions* between variables, particularly conditional relevance. Conditional relevance occurs if a factor is relevant only when it is conditioned upon some other factor. For example, only if a certain condition is met by the first high-level attribute is a second attribute taken into consideration. The same holds for the next attribute in the tree hierarchy, and so on.

Another possible benefit for financial modelers using CART is the diversification of model risk as argued by Philpotts et al. (2011). The widespread use of linear modeling methodologies among quantitative asset managers, taken together with the similarity in data sources and risk models, may in turn have contributed to model risk in financial markets leading to a high degree of commonality in investment decisions. As a less used technique, CART is appealing in the context of potentially offering a degree of model diversification. Philpotts et al. (2011) present empirical evidence highlighting the favorable performance of tree-based models compared to more traditional modeling techniques.

One potential weakness of the recursive partitioning tree construction process is local optimization instead of global optimization. That is, the sequential node-splitting process chooses the next split without attempting to optimize the performance of the whole tree. The resulting tree structure therefore does not guarantee global optimization. Instability is another possible problem in CART solutions. This refers to perturbing a small proportion of the learning sample or resampling the learning sample, which often results in a solution with a very different tree structure. Several alternatives to CART have been developed to address these

problems, such as random forests (see Brieman, 2001) and a hybrid approach that combines CART with logistic regression (see Zhu et al., 2011).

APPLICATION OF CART IN STOCK SELECTION

In this section, we provide a detailed example of the CART algorithm as applied to the problem of identifying profitable stocks. This example was specifically chosen so as to provide a contrast with the vast majority of the linear modeling techniques used by financial practitioners. The model was built with monthly stock data from December 1986 to August 2010 covering all liquid stocks listed on the North American equity markets but excluding financial stocks because they would require their own specific model.¹ The number of total observations is 279,188 (or 980 stocks per month on average).

At the end of each month, forward total stock returns (price return plus dividends) were calculated. Using the median return of all sample companies in the same period as a proxy of the market return, the excess returns were then computed as the total returns minus the market returns.

A broad spectrum of company valuation and quality-based characteristics, as well as measures of investor sentiment such as price momentum and earnings revisions were selected as reported in Table 1. Instead of using raw values, we use rank orders in order to improve the robustness of the analyses. At each month, the rank order for each variable was computed by first ranking n stocks according to the corresponding variable value, and then dividing the rank by n to scale it between 0 and 1. Furthermore, in order to overcome the high correlation among some of the explanatory variables, nine composite factors were promoted as potential explanatory variables, which were constructed as an equally weighted average of multiple variables as described in Table 1.

Table 1 Input Variables

Composite factor	Description
Value (VAL)	An equally weighted average of value metrics including dividends to price, cash flow to price, sales to price, and book to price.
Profitability (PROF)	An equally weighted average of profitability terms including return on equity, cash return on equity, pretax margins, and asset turnover.
Leverage (LEVERAGE)	An equally weighted average of financial strength terms including debt to equity and debt to market cap.
Debt Service (DEBT.SERVICE)	An equally weighted average of debt sustainability measures including interest cover and free cash flow to debt.
Momentum (MOM)	An equally weighted average of momentum terms measured over various time horizons including 6 months and 12 months.
Stability (STAB)	A composite term that captures the volatility in earnings, sales, and cash flows over the previous 5 years.
Historic Growth (HIST.GROWTH)	An equally weighted average of 3-year historic growth in earnings, sales, and cash flow.
Forward Growth (FWD.GROWTH)	An equally weighted average of I/B/E/S forecasted earnings growth expectation for FY1 and FY2.
Earnings Revisions (EREV)	An equally weighted average of the 3-month change in I/B/E/S forecasted earnings expectations for FY1 and FY2.

We built a classification tree with the purpose of predicting subsequent stock performance. Stocks were sorted into two groups, “outperformers” for those with positive excess returns and “underperformers” for the remainder. The induced categorical variable was then used as the dependent variable in the subsequent modeling process. One of the benefits of working with categorical responses instead of raw returns lies in the fact that it alleviates the impact of extreme returns, which may have multiple causes. The tree model was built with the data up to and including April 2007 while the data between May 2007 and August 2010 were reserved for out-of-sample testing. Figure 2 graphically illustrates the *hierarchical structure* of the stock selection tree.

The first observation to note is that the primary split is valuation based. More specifically, the tree makes a distinction between those stocks that are relatively expensive (the right-hand branch) and those that are not expensive. One of the most attractive nodes splits again on high value and therefore identifies cheap

stocks as having a 59.2% probability of outperforming the universe (Node 1). In contrast, the worst performing stocks are characterized by being expensive and exhibiting low profitability (Node 14). Companies with these attributes only have a 42% chance of outperforming.

The tree is able to identify the exception to the rule. For example, while identifying that value was the most important driver of stock returns, the tree also suggests that more expensive stocks still have a good chance of outperforming the market providing that they are blessed with profitability, stability in earnings, strong momentum, and are also associated with strong earnings revisions (Node 10).

Similarly, the decision tree framework also highlights the nonlinear behavior of the stock returns to the underlying predictor variables. For example, stocks in Nodes 3 and 5 have similar outperforming probabilities but are of opposite preference with regard to leverage. Conditional on above-average debt cover, Node 3 actually prefers some degree of leverage and more significantly penalizes overly

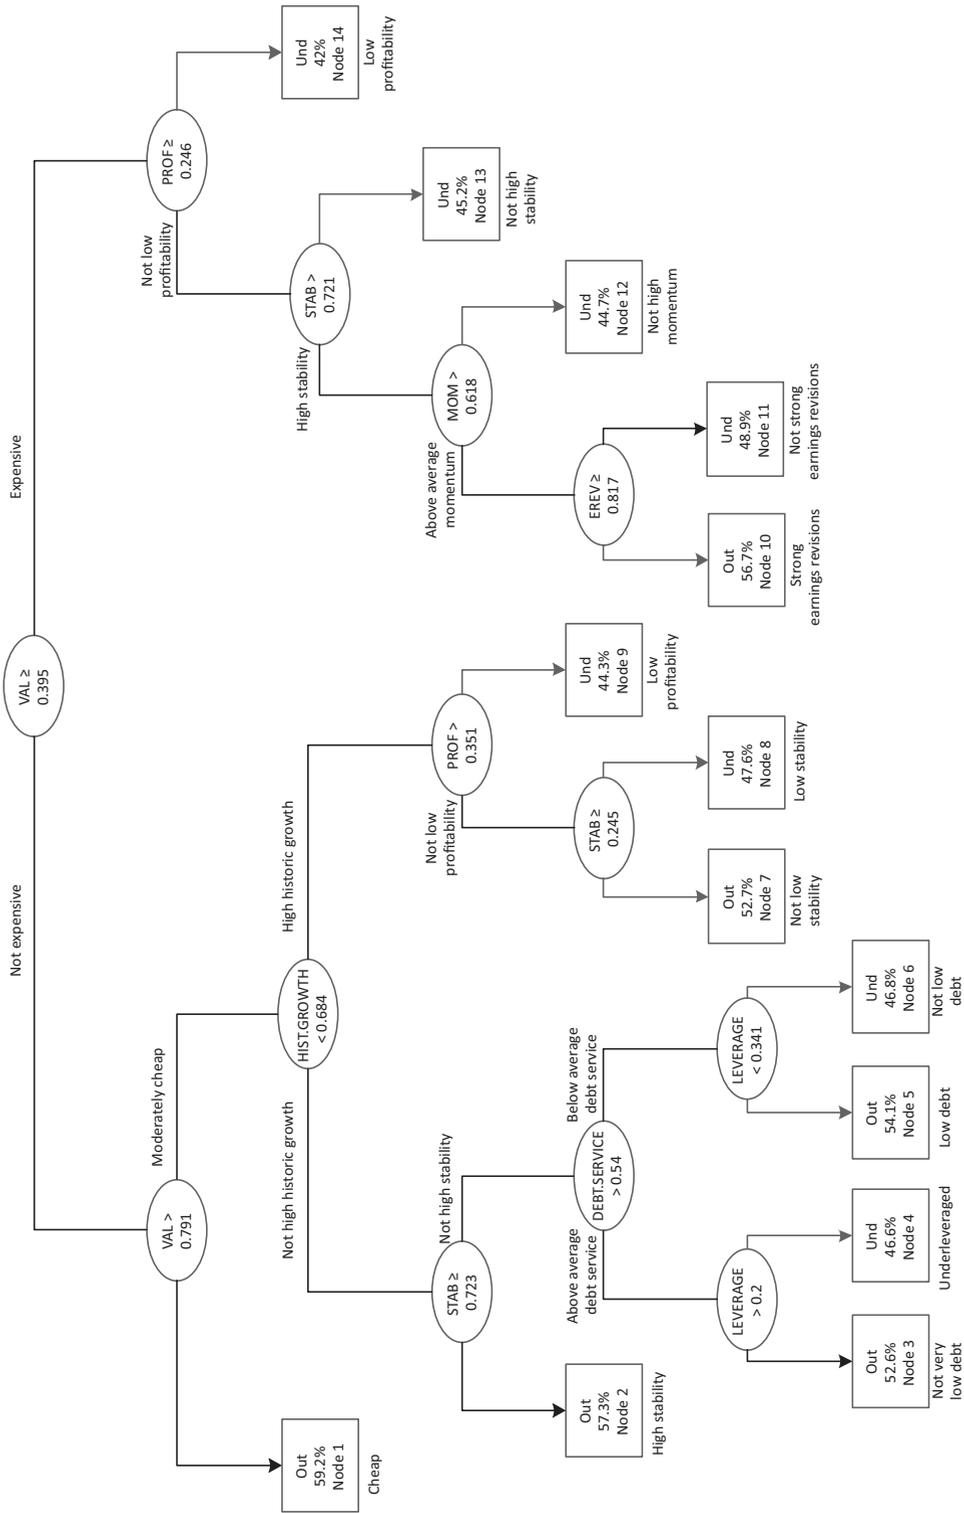

Figure 2 Decision Tree for North American stocks built using data from December 1986 to April 2007 to model the chance of a stock outperforming the overall market. The dependent variable is set as an “outperformer” (Out) if a stock subsequently achieves a higher return than the market, and “underperformer” (Und) otherwise. The outperforming probabilities are reported in percentages at each terminal node along with the splitting criteria.

Table 2 Out-of-Sample Performance (May 2007–August 2010). Portfolios were rebalanced monthly and transaction costs were not taken into account.

Portfolio	Excess Return (%)	Tracking Error (%)	IR	Monthly Win Rate
Long	2.6	2.9	0.89	0.57
Short	−2.8	3.4	−0.82	0.43

conservative firms (with too low leverage). In contrast, leverage is a characteristic to be avoided among firms that cannot service their debts (Node 5).

Table 2 is an out-of-sample test of the model. Each month from May 2007 until August 2010, we ranked all stocks based upon the predicted outperforming probabilities by the tree model and formed two portfolios. One portfolio is an equal weighting of stocks with the highest half of outperforming probabilities (long), and the second is an equal weighting of the rest expected to underperform (short). Table 2 reports the annualized excess return, the tracking error, the information ratio, and the monthly win rate of the two portfolios. The long portfolio outperformed the benchmark by 2.6% with a similar relative risk. The short portfolio underperformed by 2.8% with a slightly higher tracking error. The monthly win rate is the proportion of months that a portfolio outperformed the benchmark out-of-sample. The tree model achieved a monthly win rate of 57%.

KEY POINTS

- CART is a flexible modeling technique that offers significant potential to assist in financial decision making.
- CART is a nonparametric modeling technique that does not impose the stringent assumptions required by classical regression analysis, and therefore sidesteps many of the known issues associated with traditional parametric models.
- CART is well suited to identifying nonlinearities and complex interactions in the data. It

is minimally affected by missing values, outliers, or multicollinearity.

- Unlike many other methods, CART can be easily visualized, which helps financial decision makers to assess the theoretical support behind the resulting investment insights.
- The hierarchical structure of a tree model may more closely resemble how the human brain makes decisions. In particular, the “if-then-else” nature of the rules in the model emulates an expert system that is able to incorporate the exception to the rule.
- CART also embraces the important feature of conditional relevance, which is widespread in financial data. In the CART framework, input variables are allowed to interact and have different influences under varying conditions.
- As with any other quantitative model development process, care must be taken to ensure the integrity of the input data and that the intended application makes intuitive sense.

NOTE

1. Financial stocks were excluded due to their different accounting structure, which makes comparisons with nonfinancials troublesome, although similarly structured stock selection models can also be applied within the sector.

Applying Cointegration to Problems in Finance

BALA ARSHANAPALLI, PhD

Professor of Finance, Indiana University Northwest

WILLIAM NELSON, PhD

Professor of Finance, Indiana University Northwest

Abstract: Financial time series data tend to exhibit stochastic trends. To uncover relationships among financial variables it is important to model changes in stochastic trends over time. Cointegration can be used to identify common stochastic trends among different financial variables. If financial variables are cointegrated, it can also be shown that the variables exhibit a long-run relationship. If this long-run relationship is severed, this may indicate the presence of a financial bubble.

The long-term relationships among economic variables, such as short-term versus long-term interest rates, or stock prices versus dividends, have long interested finance practitioners. For certain types of trends, multiple regression analysis needs modification to uncover these relationships. A trend represents a long-term movement in the variable. One type of trend, a *deterministic trend*, has a straightforward solution. Since a deterministic trend is a function of time, we merely include this time function in the regression. For example, if the variables are increasing or decreasing as a linear function of time, we may simply include time as a variable in the regression equation. The issue becomes more complex when the trend is stochastic. A stochastic trend is defined (Stock and Watson, 2003) as “a persistent but random long-term movement of the variable over time.” Thus a variable with a stochastic trend may

exhibit prolonged long-run increases followed by prolonged long-run declines and perhaps another period of long-term increases.

Most financial theorists believe stochastic trends better describe the behavior of financial variables than deterministic trends. For example, if stock prices are rising, there is no reason to believe they will continue to do so in the future. Or, even if they continue to increase in the future, they may not do so at the same rate as in the past. This is because stock prices are driven by a variety of economic factors and the impact of these factors may change over time. One way of capturing these common stochastic trends is by using an econometric technique usually referred to as *cointegration*.

In this entry, we explain the concept of cointegration. There are two major ways of testing for cointegration. We outline both econometric methods and the underlying theory for each

method. We illustrate the first technique with an example of the first type of cointegration problem, testing market efficiency. Specifically, we examine the present value model of stock prices. We illustrate the second technique with an example of the second type of cointegration problem, examining market linkages. In particular, we test the linkage and the dynamic interactions among stock market indexes of three European countries. Finally, we also use cointegration to test for the presence of an asset price bubble. Specifically, we test for the possibility of bubbles in the real estate markets.

STATIONARY AND NONSTATIONARY VARIABLES AND COINTEGRATION

The presence of stochastic trends may lead a researcher to conclude that two economic variables are related over time when in fact they are not. This problem is referred to as spurious regression. For example, during the 1980s the U.S. stock market and the Japanese stock market were both rising. An ordinary least squares (OLS) regression of the U.S. Morgan Stanley Stock Index on the Japanese Morgan Stanley Stock Index (USD) for the time period 1980–1990 using monthly data yields

$$\text{Japanese Stock Index} = 76.74 + 19 \text{ U.S.}$$

Stock Index

$$t\text{-statistic } (-13.95) \quad (26.51) \quad R\text{-square} = 0.86$$

The t -statistic on the slope coefficient (26.51) is quite large, indicating a strong positive relationship between the two stock markets. This strong relationship is reinforced with a very high R-square value. However, estimating the same regression over a different time period, 1990–2007, reveals

$$\text{Japanese Stock Index} = 2905.67 - 0.29 \text{ U.S.}$$

Stock Index

$$t\text{-statistic } (30.54) \quad (-2.80) \quad R\text{-square} = 0.04$$

This regression equation suggests there is a strong negative relationship between the two stock market indexes. Although the t -statistic on the slope coefficient (2.80) is large, the low R-square value suggests that the relationship is rather weak.

The reason behind these contradictory results is the presence of stochastic trends in both series. During the first time span, these stochastic trends were aligned, but not during the latter time span. Since different economic forces influence the stochastic trends and these forces change over time, during some periods they will line up and in some periods they will not. In summary, when the variables have stochastic trends, the OLS technique may provide misleading results—the spurious regression problem.

Another problem is that when the variables contain a stochastic trend, the t -values of the regressors no longer follow a normal distribution, even for large samples. Standard hypothesis tests are no longer valid for these nonnormal distributions.

At first, researchers attempted to deal with these problems by removing the trend through differencing these variables. That is, they focused on the change in these variables, $X_t - X_{t-1}$, rather than the level of these variables, X_t . Although this technique was successful for univariate Box-Jenkins analysis, there are two problems with this approach in a multivariate scenario. First, we can only make statements about the changes in the variables rather than the level of the variables. This will be particularly troubling if our major interest is the level of the variable. Second, if the variables are subject to a stochastic trend, then focusing on the changes in the variables will lead to a specification error in our regressions.

The cointegration technique allows researchers to investigate variables that share the same stochastic trend and at the same time avoid the spurious regression problem. Cointegration analysis uses regression analysis to study the long-run linkages among economic

variables and allows us to consider the short-run adjustments to deviations from the long-run equilibrium.

The use of cointegration in finance has grown significantly. Surveying this vast literature would take us beyond the scope of this entry. To narrow our focus, we note that cointegration analysis has been used mainly for two types of problems in finance. First, it has been used to evaluate the efficiency of financial markets in a wide variety of contexts. For example, it was used to evaluate the purchasing power parity theory (see Enders, 1988), the rational expectations theory of the term structure, the present value model of stock prices (Campbell and Shiller, 1987), and the relationship between the forward and spot exchange rates (Liu and Maddala, 1992). The second type of cointegration study investigates market linkages. For example, Hendry and Juselius (2000) examine how gasoline prices at different stations are linked to the world price of oil. Arshanapalli and Doukas (1993) investigate the linkages and dynamic interactions among stock market indexes of several countries.

Before explaining cointegration it is first necessary to distinguish between stationary and nonstationary variables. A variable is said to be stationary (more formally, weakly stationary) if its mean and variance are constant and its autocorrelation depends on the lag length, that is

$$E(X_t) = \mu, \quad \text{Var}(X_t) = \sigma^2, \quad \text{and} \\ \text{Cov}(X_t, X_{t-1}) = \gamma(l)$$

Stationary means that the variable fluctuates about its mean with constant variation. Another way to put it is that the variable exhibits mean reversion and so displays no stochastic trend. In contrast, nonstationary variables may wander arbitrarily far from the mean. Thus, only nonstationary variables exhibit a stochastic trend.

The simplest example of a nonstationary variable is a random walk. A variable is a random walk if $X_t = X_{t-1} + e_t$ where e_t is a

random error term with mean 0 and standard deviation σ . It can be shown that the standard deviation $\sigma(X_t) = t\sigma$ (see Stock and Watson, 1993), where t is time. Since the standard deviation depends on time, a random walk is nonstationary.

Nonstationary time series are often referred to as a *unit root* series. The *unit root* reflects the coefficient of the X_{t-1} term in an autoregressive relationship of order one. In higher-order autoregressive models, the condition of nonstationarity is more complex. Consider the p order autoregressive model where the a_i terms are coefficients and the L^i is the lag operator. If the sum of polynomial coefficients equals 1, then the X_t series are nonstationary and again are referred to as a unit root process.

$$(1 - a_1L^1 - \dots - a_pL^p)X_t = e_t + a_0 \quad (1)$$

If all the variables under consideration are stationary, then there is no spurious regression problem and standard OLS applies. If some of the variables are stationary, and some are nonstationary, then no economically significant relationships exist. Since nonstationary variables contain a stochastic trend, they will not exhibit any relationship with the stationary variables that lack this trend. The spurious regression problem occurs only when all the variables in the system are nonstationary.

If the variables share a common stochastic trend, we may overcome the spurious regression problem. In this case, cointegration analysis may be used to uncover the long-term relationship and the short-term dynamics. Two or more nonstationary variables are cointegrated if there exists a linear combination of the variables that is stationary. This suggests cointegrated variables share long-run links. They may deviate in the short run but are likely to get back to some sort of equilibrium in the long run. The term "equilibrium" is not the same as used in economics. To economists equilibrium means the desired amount equals the actual amount, and there is no inherent tendency to change. In contrast, equilibrium in cointegration analysis

means that if variables are apart, they show a greater likelihood to move closer together than further apart.

More formally, consider two-time series x_t and y_t . Assume that both series are nonstationary and integrated order one. (Integrated order one means that if we difference the variable one time, the resultant series is stationary.) These series are cointegrated if $z_t = x_t - ay_t$, z_t is stationary for some value of a . In the multivariate case, the definition is similar with vector notation. Let A and Y be vectors (a_1, a_2, \dots, a_n) and $(y_{1t}, y_{2t}, \dots, y_{nt})'$. Then the variables in Y are cointegrated if each of the $y_{1t} \dots y_{nt}$ are nonstationary and $Z = AY$, Z is stationary. A represents a cointegrating vector.

Cointegration represents a special case. We should not expect most nonstationary variables to be cointegrated. If two variables lack cointegration, then they do not share a long-run relationship or a common stochastic trend because they can move arbitrarily far away from each other. In terms of the present value model of stock prices, suppose stock prices and dividends lack cointegration. Then stock prices could rise arbitrarily far above the level of their dividends. This would be consistent with a stock market bubble (see Gurkaynak, 2005, for a more rigorous discussion of cointegration tests of financial market bubbles) and even if it is not a bubble, it is still inconsistent with the efficient market theory. In terms of stock market linkages, if the stock price indexes of different countries lack cointegration, then stock prices can wander arbitrarily far apart from each other. This possibility should encourage international portfolio diversification.

TESTING FOR COINTEGRATION

There are two popular methods of testing for cointegration: the Engle-Granger tests and the Johansen-Juselius tests. We discuss and illustrate both in the remainder of this entry.

Engle-Granger Cointegration Tests

The Engle-Granger cointegration test, developed by Engle and Granger (1987), involves the following four-step process:

Step 1

First determine whether the time series variables under investigation are stationary. We may consider both informal and formal methods. Informal methods entail an examination of a graph of the variable over time and an examination of the autocorrelation function. The autocorrelation function describes the autocorrelation of the series for various lags. The correlation coefficient between x_t and x_{t-i} is called the lag- i autocorrelation. For nonstationary variables, the lag one autocorrelation coefficient should be very close to one and decay slowly as the lag length increases. Thus, examining the autocorrelation function allows us to determine the *stationarity* of a variable. This method is not perfect. For stationary series that are very close to unit root processes, the autocorrelation function may exhibit the slow-fading behavior described above. If more formal methods are desired, the researcher may employ the Dickey-Fuller statistic, the augmented Dickey-Fuller statistic, or the Phillips-Perron statistic. These statistics test the hypothesis that the variables have a unit root, against the alternative that they do not (Dickey and Fuller, 1979, 1981; Phillips and Perron, 1988). The Phillips-Perron test makes weaker assumptions than both Dickey-Fuller statistics and is generally considered more reliable (Phillips and Perron, 1988). If it is determined that the variable is nonstationary and the differenced variable is stationary, proceed to step 2.

Step 2

Estimate the following regression:

$$y_t = c + dx_t + z_t \quad (2)$$

To make this concrete, let y_t represent some U.S. stock market index, x_t represents stock dividends on that stock market index, and z_t is the error term. c and d are regression parameters. For cointegration tests, the null hypothesis states that the variables lack cointegration, and the alternative claims that they are cointegrated.

Step 3

To test for cointegration, we test for stationarity in z_t . The Dickey-Fuller test is the most obvious candidate. That is, we should consider the following *autoregression* of the error term:

$$\Delta z_t = pz_{t-1} + u_t \tag{3}$$

where z_t is the estimated residual from equation (2). The test focuses on the significance of the estimated p . If the estimate of p is statistically negative, we conclude that the residuals, z_t , are stationary and reject the hypothesis of no cointegration.

The residuals of equation (3) should be checked to ensure they are white noise. If they are not, we should employ the augmented Dickey-Fuller test (ADF). The augmented Dickey-Fuller test is analogous to the Dickey-Fuller test but includes additional lags of Δz_t as shown in equation (4). The ADF test for stationarity, like the Dickey-Fuller test, tests the hypothesis of $p = 0$ against the alternative hypothesis of $p < 0$ for the equation (4):

$$\Delta z_t = pz_{t-1} + a_1\Delta z_{t-1} + \dots + a_n\Delta z_{t-n} + u_t \tag{4}$$

Generally, the OLS-produced residuals tend to have as small a sample variance as possible, thereby making residuals look as stationary as possible. Thus, the standard t -statistic or ADF statistic may reject the null hypothesis of nonstationarity too often. Hence, it is important to have correct statistics; fortunately, Engle and Yoo (1987) provide the correct statistics. Furthermore, if it is believed that the variable under investigation has a long-run growth

component, it is appropriate to test the series for stationarity around a deterministic time trend for both the DF and ADF tests. This is accomplished by adding a time trend to equations (3) or (4).

Step 4

The final step involves estimating the error-correction model. Engle and Granger (1987) showed that if two variables are cointegrated, then these variables can be described in an *error-correction* format described in the following two equations:

$$\Delta y_t = b_{10} + \sum_{i=1}^n b_{1i} \Delta y_{t-i} + \sum_{j=1}^n c_{1j} \Delta x_{t-j} + d_1(y_{t-1} - ax_{t-1}) + e_{1t} \tag{5}$$

$$\Delta x_t = b_{20} + \sum_{i=1}^n b_{2i} \Delta y_{t-i} + \sum_{j=1}^n c_{2j} \Delta x_{t-j} + d_2(y_{t-1} - ax_{t-1}) + e_{2t} \tag{6}$$

Equation (5) tells us that the changes in y_t depend on its own past changes, the past changes in x_t , and the disequilibrium between x_{t-1} and y_{t-1} ($y_{t-1} - ax_{t-1}$). The size of the error-correction term, d_1 , captures the speed of adjustment of x_t and y_t to the previous period's disequilibrium. Equation (6) has a corresponding interpretation.

The appropriate lag length is found by experimenting with different lag lengths. For each lag the Akaike information criterion (AIC), the Bayes information criterion, or the Schwarz information criterion is calculated and the lag with the lowest value of the criteria is employed.¹

The value of $(y_{t-1} - ax_{t-1})$ is estimated with the residuals from the cointegrating equation (3), z_{t-1} . This procedure is only legitimate if the variables are cointegrated. The error-correction term, z_{t-1} , will be stationary by definition if and only if they are cointegrated. The remaining terms in the equation, the lag difference of each variable, are also stationary because the levels

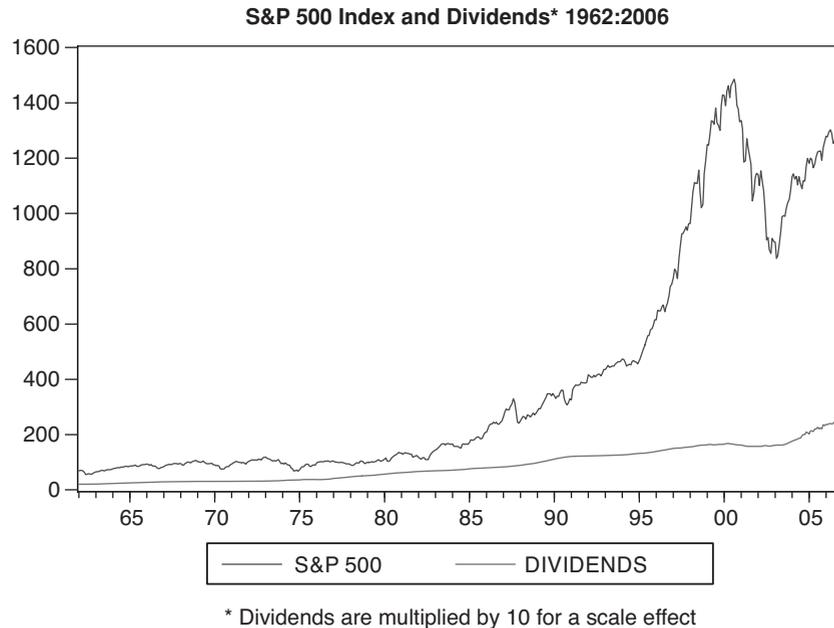

Figure 1

were assumed nonstationary. This guarantees the stationarity of all the variables in equations (5) and (6) and justifies the use of OLS.

Empirical Illustration Using the Dividend Growth Model

The dividend growth model of stock price valuation claims the fundamental value of a stock is determined by the present value of its future dividend stream. This model may be represented as:

$$P_0 = \sum d_i / (1 + r)$$

where

P_0 is the current stock price

d_i is a dividend in period i

r is the discount rate

If the discount rate exceeds the growth rate of dividends and the discount rate remains constant over time, then one can test for cointegration between stock prices and dividends. In brief, if the present value relationship holds, one

does not expect stock prices and dividends to meander arbitrarily far from each other.

Before starting any analysis it is useful to examine the plot of the underlying time series variables. Figure 1 presents a plot of stock prices and dividends for the years 1962 through 2006. The stock prices are represented by the S&P 500 index and the dividends represent the dividend received by the owner of \$1,000 worth of the S&P 500 index. The plot shows that the variables move together until the early 1980s. As a result of this visual analysis, we will entertain the possibility that the variables were cointegrated until the 1980s. After that, the common stochastic trend may have dissipated. We will first test for cointegration in the 1962–1982 period and then for the whole 1962–2006 period.

In accordance with the first step of the cointegration protocol, we must first establish the nonstationarity of the variables. To identify nonstationarity, we will use both formal and informal methods. The first informal test consists of analyzing the plot of the series shown in Figure 1. Neither series exhibits mean reversion. The dividend series wanders less

Table 1 Auto Correlation Functions of the S&P 500 Index and Dividends

Lag Auto Correlation	1	2	3	4	5	6	7	8	9	10	11	12
S&P 500	.993	.986	.979	.973	.967	.961	.954	.948	.940	.933	.926	.918
Dividend	.991	.983	.974	.966	.958	.979	.941	.933	.925	.916	.908	.900
Lag Auto Correlation	13	14	15	16	17	18	19	20	21	22	23	24
S&P 500	.911	.903	.896	.889	.881	.874	.866	.858	.851	.843	.835	.827
Dividend	.891	.883	.876	.868	.860	.852	.845	.837	.830	.822	.815	.808
Lag Auto Correlation	25	26	27	28	29	30	31	32	33	34	35	36
S&P 500	.819	.811	.804	.796	.789	.782	.775	.768	.761	.754	.748	.741
Dividend	.801	.794	.788	.781	.775	.769	.763	.758	.753	.747	.743	.738

from its mean than the stock prices. Nevertheless, neither series appears stationary.

The second informal method involves examining the autocorrelation function. We present in Table 1 the autocorrelation function for 36 lags of the S&P 500 index and the dividends for the 1962–2006 period using monthly data. The autocorrelations for the early lags are quite close to one. Furthermore, the autocorrelation function exhibits a slow decay at higher lags. This provides sufficient evidence to conclude that stock prices and dividends are nonstationary. When we inspect the autocorrelation function of their first differences (not shown), the autocorrelation of the first lag is not close to one. We may conclude the series are stationary in the first differences.

In Table 2, we present the results of formal tests of nonstationarity. The lag length for the ADF test was determined by the Schwarz criterion. The null hypothesis is that the S&P 500

stock index (dividends) contains a unit root; the alternative is that it does not. For both statistics, the ADF and the Phillips-Perron, the results indicate that the S&P 500 index is nonstationary and the changes in that index are stationary. The results for dividends are mixed. The ADF statistic supports the presence of a unit root in dividends, while the Phillips-Peron statistic does not. Since both the autocorrelation function and the ADF statistic conclude there is a unit root process, we shall presume that the dividend series is nonstationary. In sum, our analysis suggests that the S&P 500 index and dividends series each contain a stochastic trend in the levels, but not in their first differences.

In the next step of the protocol we examine whether the S&P 500 index and dividends are cointegrated. This is accomplished by estimating the long-run equilibrium relation by regressing the logarithm (log) of the S&P 500 index on the log of the dividends. We use the

Table 2 Stationarity Test for the S&P 500 Index and Dividends 1962–2006

Variable	Augmented Dickey Fuller (ADF)	Phillips-Perron	Critical Value of Test Statistics at 1%, 5%, 10% Significance
S&P 500	1.22	1.12	-3.44 (1%)
Δ S&P 500	-19.07	-19.35	-2.87 (5%)
Dividends	1.52	4.64	-2.56 (10%)
Δ Dividends	-2.13	-31.68	

Null hypothesis: Variable is nonstationary.

The lag length for the ADF test was determined by the Schwarz Criterion. For the S&P 500 index and its first difference, the lag length was 1. For the dividends and its first difference, the lag lengths were 12 and 11, respectively.

Table 3 Cointegration Regression: S&P 500 and Dividends
 $\text{Log S\&P 500} = a + b \log \text{dividends} + z_t$

Period	Constant	Coefficient of Dividends	<i>t</i> -Stat Dividends
1962–1982	4.035	.404	17.85
1962–2006	2.871	1.336	68.54

logarithms of both variables to help smooth the series. The results using monthly data are reported in Table 3 for both the 1962–1982 period and the 1962–2006 period. We pay little attention to the high *t*-statistic on the dividends variable because the *t*-test is not appropriate unless the variables are cointegrated. This is, of course, the issue.

Once we estimate the regression in step 2, the next step involves testing the residuals of the regression, z_t , for stationarity. By definition, the residuals have a zero mean and lack a time trend. This simplifies the test for stationarity. This is accomplished by estimating equation (4). The null hypothesis is that the variables lack cointegration. If we conclude that p in equation (4) is significantly negative, then we reject the null hypothesis and conclude that the evidence is consistent with the presence of cointegration between the stock index and dividends.

The appropriate lag lengths may be determined by the Akaike information criterion or theoretical and practical considerations. We decided to use a lag length of three periods representing one quarter. The results are presented in Table 4. For the 1962–1982 period, we may reject the null hypothesis of no cointegration at the 10% level of statistical significance. For the entire period (1962–2006), we cannot reject the null hypothesis ($p = 0$) of no cointegration. Apparently, the relationship between stock prices and dividends unraveled in the 1980s and the 1990s. This evidence is consistent with the existence of an Internet stock bubble in the 1990s.

Having established that the S&P 500 index and dividends are cointegrated from 1962–1982, in the final step of the protocol we examine the interaction between stock prices and dividends by estimating the error-correction model, equations (5) and (6). It is useful at this point to

Table 4 Augmented Dickey Fuller Tests of Residuals for Cointegration

Variable	Coefficient	<i>t</i> -Stat	<i>p</i> -Value
Panel A 1962–1982 $n = 248$			
z_t	-.063	-3.23	.001
Δz_{t-1}	.272	4.32	.000
Δz_{t-2}	-.030	-.46	.642
Δz_{t-3}	.090	1.40	.162
<i>t</i> -statistic of $p = -3.23$; critical values (5%) -3.36 (10%) -3.06			
Panel B 1962–2006 $n = 536$			
z_t	-.008	-1.81	.070
Δz_{t-1}	.265	6.13	.000
Δz_{t-2}	-.048	-1.08	.280
Δz_{t-3}	.031	.71	.477
<i>t</i> -statistic of $p = -1.81$; critical values (5%) 3.35 (10%) 3.05			

The critical values of the Augmented Dickey Fuller (ADF) statistic are from Engle and Yoo (1987). The cointegration equation errors used to perform the ADF test is based on the following regression:

$$\Delta z_t = -p z_{t-1} + a \Delta z_{t-1} + b \Delta z_{t-2} + c \Delta z_{t-3} + e_t$$

where Δz_t is the change in the error term from the co-integration regression and e_t is a random error. If p is positive and significantly different from zero, the z residuals from the equilibrium equation are stationary so we may accept the null hypothesis of cointegration. In both equations the error terms are white noise, so no further stationarity tests were performed.

review our interpretation of equations (5) and (6). Equation (5) claims that changes in the S&P 500 Index depend upon past changes in the S&P 500 Index and past changes in dividends and the extent of disequilibrium between the S&P 500 index and dividends. Equation (6) has a similar statistical interpretation. However, from a theoretical point of view, equation (6) is meaningless. Financial theory does not claim that changes in dividends are impacted either by past changes in stock prices or the extent of the disequilibrium between stock prices and dividends. As such, equation (6) degenerates into an autoregressive model of dividends.

We estimated the error-correction equations using three lags. The error term, z_{t-1} , used in these error-correction regressions was obtained from OLS estimation of the cointegration equation reported in Table 3. Estimates of the error-correction equations are reported in Table 5. By construction, the error-correction term represents the degree to which the stock prices and dividends deviate from long-run equilibrium. The error-correction term is included in both equations to guarantee that the variables do not drift too far apart. If the variables are cointegrated, Engle and Granger (1987) showed that the coefficient on the error-correction term ($y_{t-1} - ax_{t-1}$) in at least one of the equations must be nonzero. The t value of the error-correction term in equation (5) is statistically different

from zero. The coefficient of -0.07 is known as the speed of adjustment coefficient. It suggests that 7% of the previous month's disequilibrium between the stock index and dividends is eliminated in the current month. In general, the higher the speed of adjustment coefficient, the faster the long-run equilibrium is restored. Since the speed of adjustment coefficient for the dividend equation is statistically indistinguishable from zero, all of the adjustment falls on the stock price.

An interesting observation from Table 5 relates to the lag structure of equation (5). The first lag on past stock price changes is statistically significant. This means that the change in the stock index this month depends upon the change during the last month. This is inconsistent with the efficient market hypothesis. On the other hand, the change in dividend lags is not statistically different from zero. The efficient market theory suggests, and the estimated equation confirms, that past changes in dividends do not affect the current changes in stock prices.

Johansen-Juselius Cointegration Tests

The Engle-Granger method does have some problems (see Enders, 1995). These problems are magnified in a multivariate (three or more variables) context. In principle, when the

Table 5 Error Correction Model: S&P 500 Index and Dividends 1962-1982

$$\Delta Y_t = b_{01} + b_{11}\Delta Y_{t-2} + b_{12}\Delta Y_{t-2} + b_{13}\Delta Y_{t-3} + c_{11}\Delta X_{t-1} + c_{12}X_{t-2} + c_{13}\Delta X_{t-3} + d_1(Y_{t-1} - a X_{t-1}) + e_{1t} \quad (5)$$

$$\Delta X_{t-1} = b_{20} + b_{21}\Delta Y_{t-1} + b_{22}\Delta Y_{t-2} + b_{23}\Delta Y_{t-3} + c_{21}\Delta X_{t-1} + c_{22}\Delta X_{t-2} + c_{23}\Delta X_{t-3} + d_2(Y_{t-1} - a X_{t-1}) + e_{2t} \quad (6)$$

	Equation 5		Equation 6

c ₁₂	-.737	-.46	c ₂₂	-.005	-.06
c ₁₃	-.78	-0.65	c ₂₃	-.006	.87
d ₁	-.07	-3.64	d ₂	.000	.30

The change in the S&P 500 index is denoted as ΔY_t and the change in dividends is denoted as ΔX_t .

cointegrating equation is estimated (even in a two-variable problem), we may use any variable as the dependent variable. In our last example, this would entail placing dividends on the left-hand side of equation (2) and the S&P 500 index on the right-hand side. As the sample size approaches infinity, Engle and Granger (1987) showed the cointegration tests produce the same results irrespective of what variable you use as the dependent variable. The question then is: How large a sample is large enough?

A second problem is that the errors we use to test for cointegration are only estimates and not the true errors. Thus any mistakes made in estimating the error term, z_t , in equation (2) are carried forward into the equation (3) regression. Finally, the Engle-Granger procedure is unable to detect multiple cointegrating relationships.

The procedures developed by Johansen and Juselius (1990) avoid these problems. Consider the following multivariate model:

$$y_t = Ay_{t-1} + u_t \quad (7)$$

where

y_t is an $n \times 1$ vector ($y_{1t}, y_{2t}, \dots, y_{nt}$)'

u_t is an n -dimensional error term at t

A is an $n \times n$ matrix of coefficients

If the variables display a time trend, we may wish to add the matrix A_0 to equation (7). This would reflect a deterministic time trend. The same applies to equation (8) presented below. It does not change the nature of our analysis.

The model (without the deterministic time trend) can then be represented as:

$$\Delta y_t = (I - A)y_{t-1} + u_t \quad (8)$$

Let $B = I - A$. I is the identity matrix of dimension n . The cointegration of the system is determined by the rank of B matrix. The highest rank of B one can obtain is n , the number of variables under consideration. If the rank of the matrix equals zero, then the B matrix is null. This means $\Delta y_t = 0 + u_t$, where 0 is the null vector. In this case y_{it} will follow a random walk

($y_t = y_{t-1} + u_t$) and no linear combination of y_t will be stationary, so there are no cointegrating vectors.

If the rank of B is n , then each y_{it} is an autoregressive process. This means each y_{it} is stationary and thus they cannot be cointegrated. For any rank between 1 and $n - 1$, the system is cointegrated and the rank of the matrix is the number of cointegrating vectors.

The higher-order autoregressive representation is similar. Although it is more involved, the Johansen and Juselius estimation procedure can still handle it easily. Since the rank of a matrix equals the number of distinct nonzero characteristic roots of a matrix, the Johansen-Juselius procedure attempts to determine the number of nonzero characteristic roots of the relevant matrices. The procedure estimates the matrices and hence the characteristic roots with a maximum likelihood method.

The Johansen-Juselius procedure employs two statistics to test for nonzero characteristic roots. First they order the characteristic roots from high to low, $\lambda_1^* > \lambda_2^* > \dots > \lambda_n^*$. λ_i^* to estimate nonzero characteristic roots.

The first statistic, the trace test statistic, verifies the null hypothesis that at most i characteristic roots are different from zero. The alternative hypothesis is that more than i characteristic roots are nonzero. The statistic employed is:

$$\lambda_{\text{trace}}(i) = -T[\ln(1 - \lambda_i^*) + \ln(1 - \lambda_{i+1}^*) + \dots + \ln(1 - \lambda_n^*)]. \quad (9)$$

where T is the number of included time periods. If all the characteristic roots are zero since $\ln(1) = 0$, the statistic will equal zero. Thus low values of the test statistic will lead us to fail to reject the null hypothesis. The larger any characteristic root is, the more negative $1 - \lambda_i^*$ and the larger the test statistic and the more likely we will reject the null hypothesis.

The alternative test is called the maximum eigenvalue test since it is based on the largest eigenvalue. This statistic tests the null hypothesis that there are i cointegrating vectors against

the alternative hypothesis of $i + 1$. This statistic is:

$$\lambda_{\max}(i, i + 1) = -T \ln(1 - \lambda_{i+1}^*) \quad (10)$$

Again, if $\lambda_{i+1}^* = 0$, then the test statistic will equal zero. So low (high) values of λ_{i+1}^* will lead to a failure to reject (rejection of) the null hypothesis.

Johansen and Juselius derive critical values for both test statistics. The critical values are different if there is a deterministic time trend and an A_0 matrix is included. Enders (1995) provides tables for both critical statistics with and without the trend terms. Software programs often provide critical values and the relevant p -values.

Testing of the Dynamic Relationships among Country Stock Markets

Many portfolio managers seek international diversification. If stock market returns in different countries were not highly correlated, then portfolio managers could obtain risk reduction without significant loss of return by investing in different countries. But with the advent of globalization and the simultaneous integration of capital markets, the risk-diversifying benefits of international investing have been subject to challenge. In this section, we illustrate how cointegration can shed light on this issue and apply the Johansen-Juselius technique.

The idea of a common currency for the European countries is to reduce transactions costs and more closely link the economies. We shall use cointegration to examine whether the stock markets of France, Germany, and the Netherlands are linked following the introduction of the Euro in 1999. We use monthly data for the period 1999–2006.

The first step to test for cointegration is to establish that the three stock indexes are nonstationary in the levels and stationary in the first differences. In testing the present value model, we presented the autocorrelation function (the

ADF statistic), and the Phillips-Perron statistic. For reasons of space, we will not repeat this. Next we should establish the appropriate lag length for equation (8). This is typically done by estimating a traditional *vector autoregressive* (VAR) model and applying a multivariate version of the Akaike information criterion or Schwarz criterion. For our model, we use one lag, and thus the model takes the form:

$$y_t = A_0 + A_1 y_{t-1} + u_t \quad (11)$$

where y_t is the $n \times 3$ vector $(y_{1t}, y_{2t}, y_{3t})'$ of the logs of the stock market index for France, Germany, and the Netherlands (i.e., element y_{1t} is the log of the French index at time t ; y_{2t} is the log of the German index at time t ; and y_{3t} is the log of the Netherlands index at time t). We use logs of the stock market indexes to smooth the series. A_0 and A_1 are $n \times n$ matrices of parameters and u_t is the $n \times n$ error matrix.

The next step is to estimate the model. This means fitting equation (8). We incorporated a linear time trend, hence the inclusion of the matrix A_0 . Since there are restrictions across the equations, the procedure uses a maximum likelihood estimation procedure and not OLS. The focus of this estimation is not on the parameters of the A matrices. Few software programs present these estimates; rather, the emphasis is on the characteristic roots of the matrix B , which are estimated to determine the rank of the matrix.

The estimates of the characteristic roots are presented in Table 6. We want to establish whether i indexes are cointegrated. Thus, we test the null hypothesis that the indexes lack cointegration. To accomplish this, the λ_{trace} (0) statistic is calculated. Table 6 also provides this statistic. To ensure comprehension of this important statistic, we detail its calculation.

We have 96 usable observations.

$$\begin{aligned} \lambda_{\text{trace}}(0) &= -T[\ln(1 - \lambda_1^*) + \ln(1 - \lambda_2^*) \\ &\quad + \ln(1 - \lambda_3^*)] = -96[\ln(1 - 0.227) \\ &\quad + \ln(1 - 0.057) + \ln(1 - 0.028)] \\ &= 33.05 \end{aligned}$$

Table 6 Cointegration Test

Hypothesized No. of Cointegrating Vectors	Characteristic Roots	Trace Statistics λ_{trace}	5% Critical Value	p -Value	Max Statistic λ_{max}	5% Critical Value	p -Value
None	.227	33.05	29.80	.02	24.72	21.13	.01
At most 1	.057	8.32	15.49	.43	5.61	14.26	.66
At most 2	.028	2.72	3.84	.10	2.72	3.84	.10

As reported in Table 6, this exceeds the critical value for 5% significance of 29.80 and has a p -value of 0.02. Thus, we may reject the null hypothesis at a 5% level of significance and conclude that the evidence is consistent with at least one cointegrating vector. Next we can examine $\lambda_{\text{trace}}(1)$ to test the null hypothesis of at most 1 cointegrating vector against the alternative of 2 cointegrating vectors. Table 6 shows that λ_1 at 8.33 is less than the critical value of 15.49 necessary to establish statistical significance at the 5% level. We do not reject the null hypothesis. We therefore conclude that there is at least one cointegrating vector. There is no need to evaluate $\lambda_{\text{trace}}(2)$.

The λ_{max} statistic reinforces our conclusion. We can use $\lambda_{\text{max}}(0, 1)$ to test the null hypothesis that the variables lack cointegration against the alternative that they are cointegrated with one cointegrating vector. Table 6 presents the value of $\lambda_{\text{max}}(0, 1)$. Again, for pedagogic reasons we outline the calculation of $\lambda_{\text{max}}(0, 1)$.

$$\begin{aligned}\lambda_{\text{max}}(0, 1) &= (-T \ln(1 - \lambda_i^*)) = -96 \ln(1 - 0.227) \\ &= 24.72\end{aligned}$$

The computed value of 24.72 exceeds the critical value of 21.13 at the 5% significance level and has a p -value of 0.01. Once again, this leads us to reject the null hypothesis that the indexes lack cointegration and conclude that there exists at least one cointegrating vector.

The next step requires a presentation of the cointegrating equation and an analysis of the error-correction model. Table 7 presents both. The cointegrating equation is a multivariate representation of z_{t-1} in the Engle-Granger

method. This is presented in panel A of Table 7. The error-correction model takes the following representation.

$$\begin{aligned}\Delta y_t &= b_{10} + \sum_{i=1}^n b_{1i} \Delta y_{t-i} + \sum_{j=1}^n c_{1j} \Delta x_{t-j} \\ &\quad + d_1(y_{t-1} - ax_{t-1}) + e_{1t}\end{aligned}\quad (12)$$

The notation of equation (12) differs somewhat from the notation of equations (5) and (6). The notation used in equation (12) reflects the matrix notation adopted for the Johansen-Juselius method in equation (8). Nevertheless, for expositional convenience, we did not use the matrix notation for the error-correction term. Again, the Δ means the first difference of the variable; thus Δy_{1t-1} means the change in the log of the French stock index in period $t - 1$, $(y_{1t-1} - y_{1t-2})$. Equation (12) claims that changes in the log of the French stock index are due to changes in the French stock index during the last two (2) periods; changes in the German stock index during the last two periods; changes in the Netherlands stock index during the last two periods; and finally deviations of the French stock index from its stochastic trend with Germany and the Netherlands. An analogous equation could be written for both Germany and the Netherlands.

Panel B of Table 7 presents the error-correction model estimates for each of the three countries. The software used a two-period lag for the past values of the changes in the stock indexes as indicated by the Schwarz criterion.

The error-correction term in each equation reflects the deviation from the long-run stochastic trend of that stock index in the last period.

France (-1) represents the log return of the French stock index one month ago. Germany (-1) and Netherlands (-1) have a similar interpretation the [] represent the *t*-statistic.

It should be noted that in contrast to the two-step procedure of the Engle-Granger approach, the Johansen-Juselius approach estimates the speed of adjustment coefficient in one step. It provides insight into the short-run dynamics. This coefficient is insignificant (at the 5% level) for Germany. This means that stock prices in Germany do not change in response to deviations from their stochastic trend with France and the Netherlands. Because the variables are cointegrated, we are guaranteed that at least one speed of adjustment coefficient will be significant. In fact, the speed of adjustment coefficients of both France and the Netherlands attain statistical significance (at the 5% level) and are about the same size. This shows that when the economies of France and the Netherlands deviate from the common stochastic trend, they adjust. In France about 15% and in the Netherlands about 17% of the last-period deviation is corrected during this period.

For France, neither past changes in its own stock index nor the past changes in Germany's stock index appear to affect French stock prices.

The changes in the lagged values of both indexes lack statistical significance. Only the second lag of the Netherlands stock index attained significance. For Germany, the past changes in its own stock prices and the past changes in the stock indexes of the other countries failed to obtain significance at the 5% level. For the Netherlands, its own second-period lag obtained statistical significance. Nevertheless, the failure of individual lags to obtain significance does not mean that jointly the lags are insignificant.

To see this, we turn to an examination of *Granger causality* in the error-correction models. Granger causality helps us to classify the variables into dependent and independent. A variable Granger causes another variable when past values of that variable improve our ability to forecast the original variable. To test for Granger causality, an *F*-test is employed to verify whether the lagged changes in, say, the stock index of France jointly zero in the German equation. Table 8 reports the results of pairwise Granger causality tests. We find that France and Germany do not Granger cause each other

at any conventional levels of significance. The smaller Netherlands economy finds its stock prices Granger caused by both France and Germany but the Netherlands does not Granger cause either French or German stock prices at conventional levels of significance.

Empirical Illustration of a Test for the Presence of a Housing Bubble

The third application demonstrates the use of cointegration to test the possibility of a bubble in the housing market. As we illustrated in our previous examples, the beginning of any analysis is a picture of the time series under examination. Figure 2 shows the trend in the U.S. housing index from 1975 to the third quarter of 2007. Clearly, since 2001 the United States has experienced several years of strong home price increases. Also, the figure illustrates that the rise began to slow in 2005. At this time we know that housing prices collapsed in 2008. This sort of evidence has led the financial and the general press to conclude that the U.S. housing market has experienced a bubble. However, the detection of a bubble after the fact is of little practical use. The question is, can cointegration

provide evidence of a bubble before the bubble bursts?

The widely accepted efficient market theory claims that financial asset prices reflect all the publicly available information at all times. This denies the possibility of a bubble. While some may believe prices are too high relative to fundamental factors, according to the theory they are wrong, because investors recognize immediately if the price of anything is too high (or too low) and respond by selling (or purchasing) the asset until the over-(under) pricing is eliminated. A mountainous body of academic research (see Fama, 1970, for a sampling) supports this view.

Nevertheless, the efficient market theory has been subject to much serious criticism (Shiller, 2003). Furthermore, much of the research focused on financial assets. The efficient market theory assumes that investors can sell an asset short to eliminate overpricing. Real estate is a real and illiquid asset. During the period of the housing price run-up there was no mechanism known to us for shorting a residential home. A futures market for housing is a relatively recent innovation. These markets do not function well enough to fulfill the assumptions of the

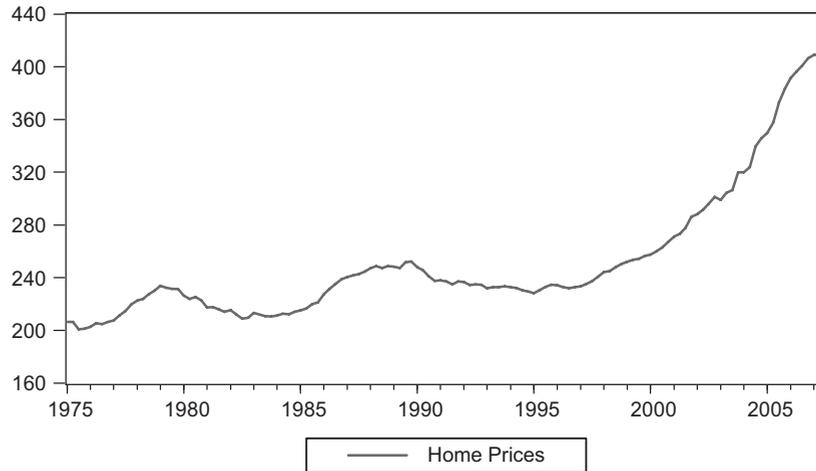

Figure 2 Home Prices in the United States

*The bursting of a real estate bubble has important implications for the U.S. economy. Residential real estate is an important component of householder wealth. In 1996, it represented 39% of household wealth. This figure is reprinted from Arshanapalli and Nelson (2008) with the permission of the Institute for Business and Finance Research.

efficient market theory. Thus, we should not dismiss the possibility of a housing bubble out of hand.

Arshanapalli and Nelson (2008) tested for the existence of a housing bubble, examining the stability of the underlying relationship of home prices and the economic forces that determine them. A relationship suddenly becomes unstable when rising home prices are not justified by the underlying economic fundamentals. Cointegration is well suited to test for this. Cointegration implies that two variables share a common stochastic trend. A common stochastic trend does not simply mean that they move upward or downward together, but rather that the variables may share both prolonged upward and prolonged downward movements.

Suppose housing prices are cointegrated with an economic variable and a bubble develops in the housing market, then housing prices rise without a corresponding rise in the variable. This implies the severing of a long-term relationship between housing prices and the variable. In other words, the cointegration should cease. In summary, if there were a housing bubble beginning in about 2000, then the variables,

which were cointegrated with housing prices before 2000, will no longer remain cointegrated after 2000.

Data

Quarterly data are used and the study covers the period 1975Q1–2007Q2. We employ the U.S. Office of Federal Housing Enterprise Oversight (OFHEO) Home Price quarterly index to measure housing prices. The index is not seasonally adjusted.

Next, we consider a series of seven variables that reflect the fundamental economic forces determining housing prices. The most important of these is income. Case and Shiller (2003) conclude that in nonbubble markets income explains most of the rise in housing prices. We employ two separate measures of income. The first is the mean of the middle quintile of the income distribution, denoted as the Middle Fifth. Second, we use the mean of the highest quintile of the income distribution, denoted as the Top Fifth. This attempts to account for the possibility that the wealthiest segment of the population influences housing prices

disproportionately because of their greater mobility. The U.S. Census Bureau, *Historical Income Tables-Families* (all races), and the National Association of Realtors provided these data.

The mortgage rate represents a strong influence on consumer demand for housing. We obtained the 30-year conventional mortgage rate (fixed rate, first mortgages) from the Board of Governors of the U.S. Federal Reserve System. The civilian unemployment rate measures the state of the economy. The U.S. Bureau of Labor Statistics provided the seasonally adjusted percentage of civilian unemployment. We converted the monthly data for both variables to quarterly data by a simple mean. The Homebuilders Stock Index provides an indication of the state of the housing market. A capitalization-weighted, price-level index of homebuilding stocks based on stocks included in the S&P 500 stock index was obtained from Merrill Lynch.

The final variables measure the ability of consumers to handle mortgage debt. The household debt ratio is the ratio of household credit market debt outstanding to annualized personal disposable income. The data also came from the Board of Governors of the U.S. Federal Reserve System. The Housing Affordability Index for all homebuyers (HAI) measures whether or not a typical family could qualify for a mortgage loan on a typical home, assuming a 20% down payment. We define a typical home as the national median-priced, existing single-family home as calculated by NAR. In its final form used here, the HAI is essentially "median family income divided by qualifying income." The index is interpreted as follows: A value of 100 means that a family with the median family income (from the U.S. Bureau of the Census and NAR) has exactly enough income to qualify for a mortgage on a median-priced home. National Association of Realtors (NAR) provided the data. In this research, the monthly HAI values result from quarterly samples.²

Again, the first step in establishing cointegration is to test the variables for stationarity. To establish nonstationarity we employed the ADF (augmented Dickey Fuller) test and the Phillips-Peron test. Although we do not display the results here, we conclude all the variables are nonstationary.

Next, we examine whether home prices and the seven fundamental variables are cointegrated. This is accomplished by examining a cointegrating regression for each of the seven variables with home prices. Table 8 presents the results of these cointegration tests for the 1975Q1–2000Q4 period. The Trace Statistic Test shows that for three of the seven variables, top fifth, middle fifth, and the unemployment rate, we may reject the null hypothesis of no cointegration at a 5% level of significance. Furthermore, we may reject the null hypothesis of no cointegration at the 10% level of statistical significance for one additional variable, the Homebuilders stock index. Thus for the period preceding the runup in home prices there appears to have been a strong link between home prices and both the income variables and the unemployment rate and a marginal link with the Homebuilders Stock Index.

Table 9 presents the results of these cointegration tests for the period 1975–2007Q3. The trace tests indicate the eigenvalues are not statistically distinguishable from zero in any equation at the 5% level. However, the P-value for the middle fifth of income was .0502. Recognizing the belief that the bubble burst in late 2005, we did the cointegration test for the period 1975–2005Q2. The P-value (hypothesized no. of CE(s) = none) for home prices vs. middle fifth of income was 11%. (Although we did not display the results, we cannot reject the hypothesis of no cointegration for any of the other fundamental variables during this period. This suggests that in the post-2005 period the normal relationship between home prices and income was reasserting itself. This result suggests that the linkage between home prices and fundamental variables has been substantially reduced

Table 9 Cointegration Test Results for the Whole Period: 1975–2007Q3

Cointegration between	Hypothesized No. of CE(s)	Eigenvalue	Trace Statistic	0.05 Critical Value	Prob. *

* Denotes the *p*-value

after 2000. The evidence is consistent with a real estate bubble.

This is consistent with the presence of an asset price bubble.

KEY POINTS

- Many of the variables of interest to finance professionals are nonstationary.
- The relationships among them can be fruitfully analyzed if they share a common stochastic trend. A way of capturing this common stochastic trend is the application of cointegration.
- Cointegration analysis can reveal interesting long-run relationships between the variables.
- It is possible that cointegrating variables may deviate in the short run from their relationship, but the error correction model shows how these variables adjust to the long-run equilibrium.
- Cointegration analysis can reveal interesting short-run asset pricing adjustments.
- The error-correction models tend to have a better forecasting performance than simple vector autoregressive models.
- Cointegration analysis shows when fundamental long-run relationships are severed.

NOTES

1. For a summary of these criteria, see Chapter 12 in Focardi and Fabozzi (2004).
2. For more details on the exact calculation, go to www.realtor.org.

Nonlinearity and Nonlinear Econometric Models in Finance

RUEY S. TSAY, PhD

H.G.B. Alexander Professor of Econometrics and Statistics,
University of Chicago Booth School of Business

Abstract: Many financial and economic data exhibit nonlinear characteristics. Prices of commodities such as crude oil often rise quickly but decline slowly. The monthly U.S. unemployment rate exhibits sharp increases followed by slow decreases. To model these characteristics in a satisfactory manner, one must employ nonlinear econometric models or use nonparametric statistical methods. For most applications, it suffices to employ simple nonlinear models. For example, the quarterly growth rate of the U.S. gross domestic product can be adequately described by the Markov switching or threshold autoregressive models. These models typically classify the state of the U.S. economy into two categories corresponding roughly to expansion and contraction.

In this entry, we study nonlinearity in financial data, discuss various nonlinear models available in the literature, and demonstrate application of nonlinear models in finance with real examples. The models discussed include bilinear models, *threshold autoregressive models*, smooth threshold autoregressive models, *Markov switching models*, and nonlinear additive autoregressive models. We also consider *nonparametric methods* and *neural networks*, and apply nonparametric methods to estimate interest models. To detect nonlinearity in financial data, we introduce various *nonlinearity tests* available in the literature and apply the tests to some financial series. Finally, we analyze the monthly U.S. unemployment rate and compare out-of-sample prediction of nonlinear models with linear ones via several criteria.

STUDY OF NONLINEARITY IN ECONOMETRICS AND STATISTICS

Assume, for simplicity, a univariate time series x_t is observed at equally spaced time points. We denote the observations by $\{x_t | t = 1, \dots, T\}$, where T is the sample size. A purely stochastic time series x_t is said to be linear if it can be written as

$$x_t = \mu + \sum_{i=0}^{\infty} \psi_i a_{t-i} \quad (1)$$

where μ is a constant, ψ_i are real numbers with $\psi_0 = 1$, and $\{a_i\}$ is a sequence of independent and identically distributed (IID) random variables with a well-defined distribution function. We assume that the distribution of a_t is

continuous and $E(a_t) = 0$. In many cases, we further assume that $\text{Var}(a_t) = \sigma_a^2$ or, even stronger, that a_t is Gaussian. If $\sigma_a^2 \sum_{i=1}^{\infty} \psi_i^2 < \infty$, then X_t is weakly stationary (i.e., the first two moments of x_t are time-invariant). The well-known autoregressive moving-average (ARMA) process of Box et al. (2008) is linear because it has an moving-average (MA) representation in equation (1). Any stochastic process that does not satisfy the condition of equation (1) is said to be nonlinear. The prior definition of nonlinearity is for purely stochastic time series. One may extend the definition by allowing the mean of x_t to be a linear function of some exogenous variables, including the time index and some periodic functions. But such a mean function can be handled easily by using a regression model with time series errors discussed in Tsay (2010, Chapter 2), and we shall not consider the extension here. Mathematically, a purely stochastic time series model for x_t is a function of an IID sequence consisting of the current and past shocks—that is,

$$x_t = f(a_t, a_{t-i}, \dots) \quad (2)$$

The linear model in equation (1) says that $f(\cdot)$ is a linear function of its arguments. Any nonlinearity in $f(\cdot)$ results in a nonlinear model. The general nonlinear model in equation (2) is too vague to be useful in practice. Further assumptions are needed to make the model applicable.

To put nonlinear models available in the literature in a proper perspective, we write the model of x_t in terms of its conditional moments. Let F_{t-1} be the σ -field generated by available information at time $t - 1$ (inclusive). Typically, F_{t-1} denotes the collection of linear combinations of elements in $\{x_{t-1}, x_{t-2}, \dots\}$ and $\{a_{t-1}, a_{t-2}, \dots\}$. The conditional mean and variance of x_t given F_{t-1} are

$$\begin{aligned} \mu_t &= E(x_t | F_{t-1}) \equiv g(F_{t-1}) \\ \sigma_t^2 &= \text{Var}(x_t | F_{t-1}) \equiv h(F_{t-1}) \end{aligned} \quad (3)$$

where $g(\cdot)$ and $h(\cdot)$ are well-defined functions with $h(\cdot) > 0$. Thus, we restrict the model to

$$x_t = g(F_{t-1}) + \sqrt{h(F_{t-1})}e_t$$

where $e_t = a_t/\sigma_t$ is a standardized shock (or innovation). For the linear series x_t in equation (1), $g(\cdot)$ is a linear function of elements of F_{t-1} and $h(\cdot) = \sigma_a^2$. The development of nonlinear models involves making extensions of the two equations in equation (3). If $g(\cdot)$ is nonlinear, x_t is said to be nonlinear in mean. If $h(\cdot)$ is time-variant, then x_t is nonlinear in variance. The conditional heteroscedastic models, for example, the GARCH model of Bollerslev (1986), are nonlinear in variance because their conditional variances σ_t^2 evolve over time. Based on the well-known Wold decomposition, a weakly stationary and purely stochastic time series can be expressed as a linear function of uncorrelated shocks. For stationary volatility series, these shocks are uncorrelated, but dependent. The models discussed in this entry represent another extension to nonlinearity derived from modifying the conditional mean equation in equation (3).

Many nonlinear time series models have been proposed in the statistical literature, such as the bilinear models of Granger and Andersen (1978), the threshold autoregressive (TAR) model of Tong (1978), the state-dependent model of Priestley (1980), and the Markov switching model of Hamilton (1989). The basic idea underlying these nonlinear models is to let the conditional mean μ_t evolve over time according to some simple parametric nonlinear function. Recently, a number of nonlinear models have been proposed by making use of advances in computing facilities and computational methods. Examples of such extensions include the nonlinear state-space modeling of Carlin, Polson, and Stoffer (1992), the functional-coefficient autoregressive model of Chen and Tsay (1993a), the nonlinear additive autoregressive model of Chen and Tsay (1993b), the multivariate adaptive regression spline of Lewis and Stevens (1991), and the generalized autoregressive score (GAS) model of Creal et al. (2010). The basic idea of these extensions is either using simulation methods to describe the evolution of the conditional

distribution of x_t or using data-driven methods to explore the nonlinear characteristics of a series. Finally, nonparametric and semiparametric methods such as kernel regression and artificial neural networks have also been applied to explore the nonlinearity in a time series. We discuss some nonlinear models in this entry that are applicable to financial time series. The discussion includes some nonparametric and semiparametric methods.

Apart from the development of various nonlinear models, there is substantial interest in studying test statistics that can discriminate linear series from nonlinear ones. Both parametric and nonparametric tests are available. Most parametric tests employ either the Lagrange multiplier or likelihood ratio statistics. Nonparametric tests depend on either higher order spectra of x_t or the concept of dimension correlation developed for chaotic time series. We review some nonlinearity tests, discuss modeling and forecasting of nonlinear models, and provide an application of nonlinear models.

NONLINEAR MODELS

Most nonlinear models developed in the statistical literature focus on the conditional mean equation in equation (3); see Priestley (1988) and Tong (1990) for summaries of nonlinear models. Our goal here is to introduce some nonlinear models that are useful in finance.

Bilinear Model

The linear model in equation (1) is simply the first-order Taylor series expansion of the $f(\cdot)$ function in equation (2). As such, a natural extension to nonlinearity is to employ the second-order terms in the expansion to improve the approximation. This is the basic idea of bilinear models, which can be defined as

$$x_t = c + \sum_{i=1}^p \phi_i x_{t-i} - \sum_{j=1}^q \theta_j a_{t-j} + \sum_{i=1}^m \sum_{j=1}^s \beta_{ij} x_{t-i} a_{t-j} + a_t \tag{4}$$

where $p, q, m,$ and s are nonnegative integers. This model was introduced by Granger and Andersen (1978) and has been widely investigated. Subba Rao and Gabr (1984) discuss some properties and applications of the model, and Liu and Brockwell (1988) study general bilinear models. Properties of bilinear models such as stationarity conditions are often derived by (a) putting the model in a state-space form and (b) using the state transition equation to express the state as a product of past innovations and random coefficient vectors. A special generalization of the bilinear model in equation (4) has conditional heteroscedasticity. For example, consider the model

$$x_t = \mu + \sum_{i=1}^s \beta_i a_{t-i} a_t + a_t \tag{5}$$

where $\{a_t\}$ is a white noise series. The first two conditional moments of x_t are

$$E(x_t | F_{t-1}) = \mu$$

$$\text{Var}(x_t | F_{t-1}) = \left(1 + \sum_{i=1}^s \beta_i a_{t-i} \right)^2 \sigma_a^2$$

which confirm that the model has time-varying volatility.

Example 1. Consider the monthly simple returns of the CRSP equal-weighted index from January 1926 to December 2008 for 996 observations. Denote the series by R_t . The sample partial autocorrelation function (PACF) of R_t shows significant serial correlations at lags 1 and 3 so that an AR(3) model is used for the mean equation. The squared series of the AR(3) residuals suggests that the conditional heteroscedasticity might depend on lags 1, 3 and 8 of the residuals. Therefore, we employ the special bilinear model

$$R_t = \mu + \phi_1 R_{t-1} + \phi_3 R_{t-3} + (1 + \beta_1 a_{t-1} + \beta_3 a_{t-3}) a_t$$

for the series, where $a_t = \beta_0 \epsilon_t$ with ϵ_t being an IID series with mean zero and variance 1. Note that lag 8 is omitted for simplicity. Assuming that the conditional distribution of a_t is normal, we use the conditional maximum

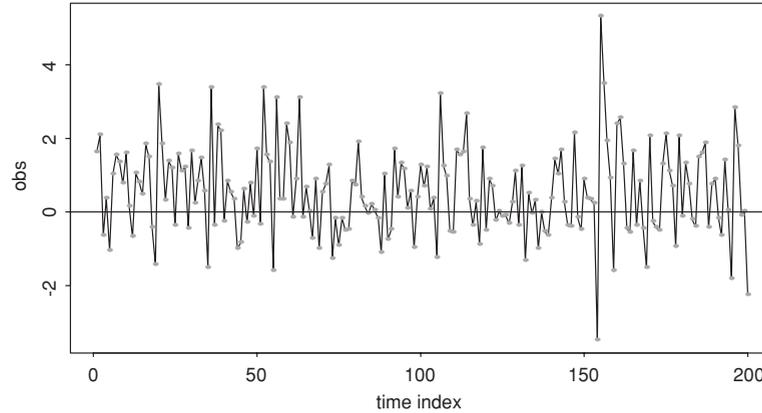

Figure 1 Time Plot of a Simulated 2-Regime TAR(1) Series

likelihood method and obtain the fitted model

$$R_t = 0.0114 + 0.167R_{t-1} - 0.095R_{t-3} + 0.071(1 + 0.377a_{t-1} - 0.646a_{t-3})\epsilon_t \quad (6)$$

where the standard errors of the parameters are, in the order of appearance, 0.0023, 0.032, 0.027, 0.002, 0.147, and 0.136, respectively. All estimates are significantly different from zero at the 5% level. Define

$$\hat{\epsilon}_t = \frac{R_t - 0.0114 - 0.167R_{t-1} + 0.095R_{t-3}}{0.071(1 + 0.377\hat{a}_{t-1} - 0.646\hat{a}_{t-3})}$$

where $\hat{\epsilon}_t = 0$ for $t \leq 3$ as the standardized residual series of the model. The sample autocorrelation function (ACF) of $\hat{\epsilon}_t$ shows no significant serial correlations, but the series is not independent because the squared series $\hat{\epsilon}_t^2$ has significant serial correlations. The validity of model (6) deserves further investigation. For comparison, we also consider an AR(3)-ARCH(3) model for the series and obtain

$$R_t = 0.013 + 0.223R_{t-1} + 0.006R_{t-2} - 0.013R_{t-3} + a_t \quad (7)$$

$$\sigma_t^2 = 0.002 + 0.185a_{t-1}^2 + 0.301a_{t-2}^2 + 0.197a_{t-3}^2$$

where all estimates but the coefficients of R_{t-2} and R_{t-3} are highly significant. The standardized residual series of the model shows no serial correlations, but the squared residuals show $Q(10) = 19.78$ with a p -value of 0.031. Models (6) and (7) appear to be similar, but the latter seems

to fit the data better. Further study shows that an AR(1)-GARCH(1,1) model fits the data well.

Threshold Autoregressive (TAR) Model

This model is motivated by several nonlinear characteristics commonly observed in practice such as asymmetry in declining and rising patterns of a process. It uses piecewise linear models to obtain a better approximation of the conditional mean equation. However, in contrast to the traditional piecewise linear model that allows for model changes to occur in the “time” space, the TAR model uses threshold space to improve linear approximation. Let us start with a simple 2-regime AR(1) model

$$x_t = \begin{cases} -1.5x_{t-1} + a_t & \text{if } x_{t-1} < 0 \\ 0.5x_{t-1} + a_t & \text{if } x_{t-1} \geq 0 \end{cases} \quad (8)$$

where the a_t are IID $N(0,1)$. Here the threshold variable is x_{t-1} and the threshold is 0.

Figure 1 shows the time plot of a simulated series of x_t with 200 observations. A horizontal line of zero is added to the plot, which illustrates several characteristics of TAR models. First, despite the coefficient -1.5 in the first regime, the process x_t is geometrically ergodic and stationary. In fact, the necessary and sufficient condition for model (8) to be geometrically ergodic is $\phi_1^{(1)} < 1$, $\phi_1^{(2)} < 1$ and $\phi_1^{(1)} \phi_1^{(2)} < 1$, where

$\phi_1^{(i)}$ is the AR coefficient of regime i ; see Petrucci and Woolford (1984) and Chen and Tsay (1991).

Ergodicity is an important concept in time series analysis. For example, the statistical theory showing that the sample mean $\bar{x} = (\sum_{t=1}^T x_t)/T$ of x_t converges to the mean of x_t is referred to as the ergodic theorem, which can be regarded as the counterpart of the central limit theory for the IID case. Second, the series exhibits an asymmetric increasing and decreasing pattern. If x_{t-1} is negative, then x_t tends to switch to a positive value due to the negative and explosive coefficient -1.5 . Yet when x_{t-1} is positive, it tends to take multiple time periods for x_t to reduce to a negative value. Consequently, the time plot of x_t shows that regime 2 has more observations than regime 1, and the series contains large upward jumps when it becomes negative. The series is therefore not time-reversible. Third, the model contains no constant terms, but $E(x_t)$ is not zero. The sample mean of the particular realization is 0.61 with a standard deviation of 0.07. In general, $E(x_t)$ is a weighted average of the conditional means of the two regimes, which are nonzero. The weight for each regime is simply the probability that x_t is in that regime under its stationary distribution. It is also clear from the discussion that, for a TAR model to have zero mean, nonzero constant terms in some of the regimes are needed. This is very different from a stationary linear model for which a nonzero constant implies that the mean of x_t is not zero.

A time series x_t is said to follow a k -regime self-exciting TAR (SETAR) model with threshold variable x_{t-d} if it satisfies

$$x_t = \phi_0^{(j)} + \phi_1^{(j)} x_{t-1} - \dots - \phi_p^{(j)} x_{t-p} + a_t^{(j)} \quad (9)$$

if $\gamma_{j-1} \leq x_{t-d} < \gamma_j$

where k and d are positive integers, $j = 1, \dots, k$, γ_i are real numbers such that $-\infty = \gamma_0 < \gamma_1 < \dots < \gamma_{k-1} < \gamma_k = \infty$, the superscript (j) is used to signify the regime, and $\{a_t^{(j)}\}$ are IID sequences with mean 0 and variance σ_j^2 and are mutually independent for different j . The parameter d is referred to as the delay pa-

rameter and γ_j are the thresholds. Here it is understood that the AR models are different for different regimes; otherwise, the number of regimes can be reduced. Equation (9) says that a SETAR model is a piecewise linear AR model in the threshold space. It is similar in spirit to the usual piecewise linear models in regression analysis, where model changes occur in the order in which observations are taken. The SETAR model is nonlinear provided that $k > 1$.

Properties of general SETAR models are hard to obtain, but some of them can be found in Tong (1990), Chan (1993), Chan and Tsay (1998), and the references therein. In recent years, there is increasing interest in TAR models and their applications; see, for instance, Hansen (1997), Tsay (1998), and Montgomery et al. (1998). Tsay (1989) proposed a testing and modeling procedure for univariate SETAR models. The model in equation (9) can be generalized by using a threshold variable z_t that is measurable with respect to F_{t-1} (i.e., a function of elements of F_{t-1}). The main requirements are that z_t is stationary with a continuous distribution function over a compact subset of the real line and that z_{t-d} is known at time t . Such a generalized model is referred to as an open-loop TAR model.

Example 2. To demonstrate the application of TAR models, consider the U.S. monthly civilian unemployment rate, seasonally adjusted and measured in percentage, from January 1948 to March 2009 for 735 observations. The data are obtained from the Bureau of Labor Statistics, Department of Labor, and are shown in Figure 2. The plot shows two main characteristics of the data. First, there appears to be a slow but upward trend in the overall unemployment rate. Second, the unemployment rate tends to increase rapidly and decrease slowly. Thus, the series is not time-reversible and may not be unit-root stationary, either.

Because the sample autocorrelation function decays slowly, we employ the first differenced series $y_t = (1-B)u_t$ in the analysis, where u_t is the monthly unemployment rate. Using

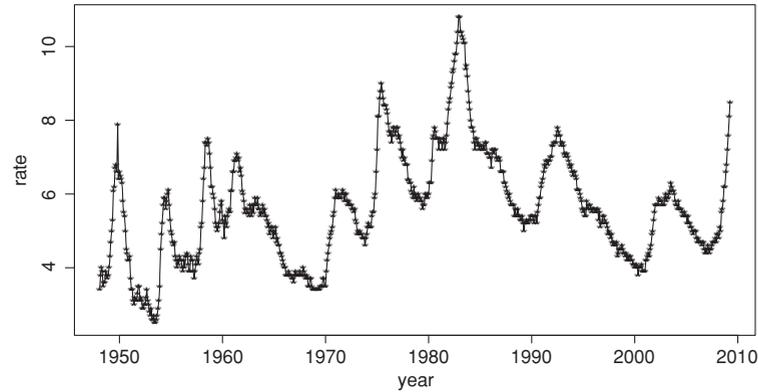

Figure 2 Time Plot of Monthly U.S. Civilian Unemployment Rate, Seasonally Adjusted, from January 1948 to March 2009

univariate ARIMA models, we obtain the model

$$\begin{aligned} (1 - 1.13B + 0.27B^2)(1 - 0.51B^{12})y_t \\ = (1 - 1.12B + 0.44B^2)(1 - 0.82B^{12})a_t \end{aligned} \quad (10)$$

where $\hat{\sigma}_a = 0.187$ and all estimates but the AR(2) coefficient are statistically significant at the 5% level. The t-ratio of the estimate of AR(2) coefficient is -1.66 . The residuals of model (10) give $Q(12) = 12.3$ and $Q(24) = 25.5$, respectively. The corresponding p -values are 0.056 and 0.11, respectively, based on χ^2 distributions with 6 and 18 degrees of freedom. Thus, the fitted model adequately describes the serial dependence of the data. Note that the seasonal AR and MA coefficients are highly significant with standard error 0.049 and 0.035, respectively, even though the data were seasonally adjusted. The adequacy of seasonal adjustment deserves further study. Using model (10), we obtain the 1-step ahead forecast of 8.8 for the April 2009 unemployment rate, which is close to the actual data of 8.9.

To model nonlinearity in the data, we employ TAR models and obtain the model

$$y_t = \begin{cases} 0.083y_{t-2} + 0.158y_{t-3} + 0.118y_{t-4} \\ \quad - 0.180y_{t-12} + a_{1t} & \text{if } y_{t-i} \leq 0.1 \\ 0.421y_{t-2} + 0.239y_{t-3} - 0.127y_{t-12} \\ \quad + a_{2t} & \text{if } y_{t-i} > 0.1 \end{cases} \quad (11)$$

where the standard errors of a_{it} are 0.180 and 0.217, respectively, the standard errors of the AR parameters in regime 1 are 0.046, 0.043, 0.042, and 0.037 whereas those of the AR parameters in regime 2 are 0.054, 0.057, and 0.075, respectively. The number of data points in regimes 1 and 2 are 460 and 262, respectively. The standardized residuals of model (11) only shows some minor serial correlation at lag 12. Based on the fitted TAR model, the dynamic dependence in the data appears to be stronger when the change in monthly unemployment rate is greater than 0.1%. This is understandable because a substantial increase in the unemployment rate is indicative of weakening in the U.S. economy, and policy makers might be more inclined to take action to help the economy, which in turn may affect the dynamics of the unemployment rate series. Consequently, model (11) is capable of describing the time-varying dynamics of the U.S. unemployment rate.

The MA representation of model (10) is

$$\begin{aligned} \psi(B) \approx 1 + 0.01B + 0.18B^2 + 0.20B^3 \\ + 0.18B^4 + 0.15B^5 + \dots \end{aligned}$$

It is then not surprising to see that no y_{t-1} term appears in model (11).

Threshold models can be used in finance to handle the leverage effect, that is, volatility responds differently to prior positive and negative returns. The models can also be used to

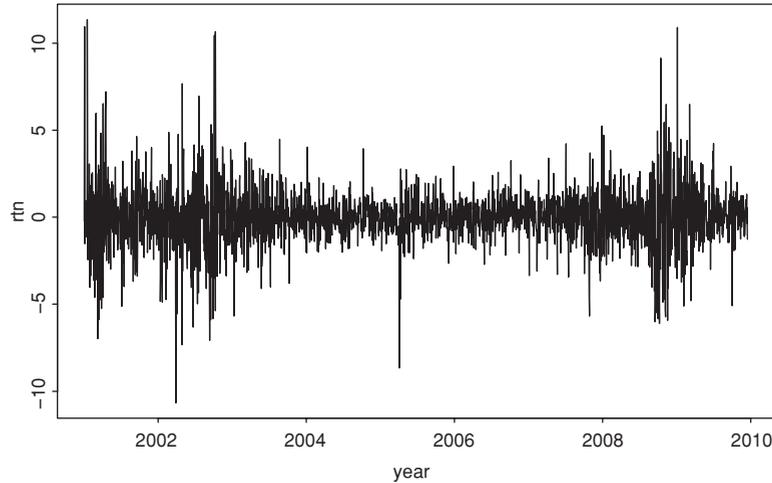

Figure 3 Time Plot of the Daily Log Returns, in Percentages, for IBM Stock from January 2, 2001 to December 31, 2009

study arbitrage trading in index futures and cash prices. See Tsay (2010, chap. 8) for discussions and demonstration. Here we focus on volatility modeling and introduce an alternative approach to parameterization of threshold GARCH (TGARCH) models. In some applications, this new general TGARCH model fares better than the model of Glosten et al. (1993).

Example 3. Consider the daily log returns, in percentages and including dividends, of IBM stock from January 2, 2001 to December 31, 2009 for 2,263 observations. Figure 3 shows the time plot of the series. The volatility seems to be larger at the beginning and end of the data span. If GARCH models are entertained, we obtain the following GARCH(1,1) model for the series:

$$\begin{aligned} r_t &= 0.058 + a_t, & a_t &= \sigma_t \epsilon_t \\ \sigma_t^2 &= 0.041 + 0.093a_{t-1}^2 + 0.894\sigma_{t-1}^2 \end{aligned} \quad (12)$$

where r_t is the log return, $\{\epsilon_t\}$ is a Gaussian white noise sequence with mean zero and variance 1.0, the standard error of the constant term in the mean equation is 0.026, and those of the volatility equation are 0.012, 0.020, and 0.021, respectively. All estimates are statistically significant at the 5% level. The Ljung-Box statistics of the standardized

residuals, $\hat{\epsilon}_t = \hat{a}_t / \hat{\sigma}_t$, give $Q(10) = 10.08(0.43)$ and $Q(20) = 23.24(0.28)$, where the number in parentheses denotes p -value obtained using the asymptotic X_m^2 distribution. For the squared standardized residuals, we obtain $Q(10) = 7.38(0.69)$ and $Q(20) = 15.43(0.75)$. The model is adequate in modeling the serial dependence and conditional heteroscedasticity of the data. But the unconditional mean for r_t of model (12) is 0.058, which is substantially larger than the sample mean 0.024, indicating that the model might be misspecified.

Next, we employ the TGARCH model of Glosten et al. (1993) and obtain

$$\begin{aligned} r_t &= 0.015 + a_t, & a_t &= \sigma_t \epsilon_t \\ \sigma_t^2 &= 0.032 + 0.033a_{t-1}^2 + 0.091N_{t-1}a_{t-1}^2 \\ &\quad + 0.911\sigma_{t-1}^2 \end{aligned} \quad (13)$$

where N_{t-1} is the indicator for negative a_{t-1} such that $N_{t-1} = 1$ if $a_{t-1} < 0$ and $= 0$ otherwise, the standard error of the parameter in the mean equation is 0.026, and those of the volatility equation are 0.005, 0.005, 0.006, and 0.008, respectively. All estimates except the constant term of the mean equation are highly significant. Let \tilde{a}_t be the standardized residuals of model (13). We have $Q(10) = 9.81(0.46)$ and $Q(20) = 22.17(0.33)$ for the $\{\tilde{a}_t\}$ series and

$Q(10) = 22.12(0.01)$ and $Q(20) = 31.15(0.05)$ for $\{\hat{a}_t^2\}$. The model fails to describe the conditional heteroscedasticity of the data at the 5% level.

The idea of TAR models can be used to refine the prior TGARCH model by allowing for increased flexibility in modeling the asymmetric response in volatility. More specifically, we consider a TAR-GARCH(1,1) model for the series and use the constrained optimization method L-BFGS-B to perform estimation. The resulting model is

$$\begin{aligned} r_t &= 0.023 + a_t, \quad a_t = \sigma_t \epsilon_t \\ \sigma_t^2 &= 0.086 + 0.044a_{t-1}^2 + 0.815\sigma_{t-1}^2 \\ &\quad + (-0.114 + 0.052a_{t-1}^2 + 0.214\sigma_{t-1}^2)N_{t-1} \end{aligned} \quad (14)$$

where all estimates are significant at the 5% level and N_{t-1} is defined in equation (13). The estimate -0.114 is only marginally significant because its standard error is 0.055. The coefficient of σ_{t-1}^2 is greater than 1 when $a_{t-1} < 0$, but it is not significantly different from 1 in view of its standard error.

Let \hat{a}_t be the standardized residuals of model (14). We obtain $Q(10) = 9.10(0.52)$ and $Q(20) = 21.82(0.35)$ for $\{\hat{a}_t\}$ and $Q(10) = 19.80(0.03)$ and $Q(20) = 27.41(0.12)$ for $\{\hat{a}_t^2\}$. Thus, model (14) is adequate in modeling the serial correlation and conditional heteroscedasticity of the daily log returns of IBM stock considered. The unconditional mean return of model (14) is 0.023, which is much closer to the sample mean 0.024 than those implied by models (12) and (13). Comparing the fitted TAR-GARCH and TGARCH models, we see that the asymmetric behavior in daily IBM stock volatility is much stronger than what is allowed in a TGARCH model. Specifically, the coefficient of σ_{t-1}^2 also depends on the sign of a_{t-1} .

Smooth Transition AR (STAR) Model

A criticism of the SETAR model is that its conditional mean equation is not continuous. The

thresholds $\{\gamma_j\}$ are the discontinuity points of the conditional mean function μ_t . In response to this criticism, smooth TAR models have been proposed; see Chan and Tong (1986) and Teräsvirta (1994) and the references therein. A time series x_t follows a 2-regime STAR(p) model if it satisfies

$$\begin{aligned} x_t &= c_0 + \sum_{i=1}^p \phi_{0,i} x_{t-i} + F\left(\frac{x_{t-d} - \Delta}{s}\right) \\ &\quad \times \left(c_1 + \sum_{i=1}^p \phi_{1,i} x_{t-i}\right) + a_t \end{aligned} \quad (15)$$

where d is the delay parameter, Δ and s are parameters representing the location and scale of model transition, and $F(\cdot)$ is a smooth transition function. In practice, $F(\cdot)$ often assumes one of three forms—namely, logistic, exponential, or a cumulative distribution function. From equation (15) and with $0 \leq F(\cdot) \leq 1$, the conditional mean of a STAR model is a weighted linear combination between the following two equations:

$$\begin{aligned} \mu_{1t} &= c_0 + \sum_{i=1}^p \phi_{0,i} x_{t-i} \\ \mu_{2t} &= (c_0 + c_1) + \sum_{i=1}^p (\phi_{0,i} + \phi_{1,i}) x_{t-i} \end{aligned}$$

The weights are determined in a continuous manner by $F((x_{t-d} - \Delta)/s)$. The prior two equations also determine properties of a STAR model. For instance, a prerequisite for the stationarity of a STAR model is that all zeros of both AR polynomials are outside the unit circle. An advantage of the STAR model over the TAR model is that the conditional mean function is differentiable. However, experience shows that the transition parameters Δ and s of a STAR model are hard to estimate. In particular, most empirical studies show that standard errors of the estimates of Δ and s are often quite large, resulting in t -ratios about 1.0; see Teräsvirta (1994). This uncertainty leads to various complications in interpreting an estimated STAR model.

Example 4. To illustrate the application of STAR models in financial time series analysis,

we consider the monthly simple stock returns for Minnesota Mining and Manufacturing (3M) Company from February 1946 to December 2008. If ARCH models are entertained, we obtain the following ARCH(2) model

$$\begin{aligned} R_t &= 0.013 + a_t, \quad a_t = \sigma_t \epsilon_t \\ \sigma_t^2 &= 0.003 + 0.088a_{t-1}^2 + 0.109a_{t-2}^2 \end{aligned} \quad (16)$$

where standard errors of the estimates are 0.002, 0.0003, 0.047, and 0.050, respectively. As discussed before, such an ARCH model fails to show the asymmetric responses of stock volatility to positive and negative prior shocks. The STAR model provides a simple alternative that may overcome this difficulty. Applying STAR models to the monthly returns of 3M stock, we obtain the model

$$\begin{aligned} R_t &= 0.015 + at, \quad a_t = \sigma_t \epsilon_t \\ \sigma_t^2 &= (0.003 + 0.205a_{t-1}^2 + 0.092a_{t-2}^2) \\ &\quad + \frac{0.001 - 0.239a_{t-1}^2}{1 + \exp(-1000a_{t-1})} \end{aligned} \quad (17)$$

where the standard error of the constant term in the mean equation is 0.002 and the standard errors of the estimates in the volatility equation are 0.0002, 0.074, 0.043, 0.0004, and 0.080, respectively. The scale parameter 1000 of the logistic transition function is fixed a priori to simplify the estimation. This STAR model provides some support for asymmetric responses to positive and negative prior shocks. For a large negative a_{t-1} , the volatility model approaches the ARCH(2) model

$$\sigma_t^2 = 0.003 + 0.205a_{t-1}^2 + 0.092a_{t-2}^2$$

Yet for a large positive a_{t-1} , the volatility process behaves like the ARCH(2) model

$$\sigma_t^2 = 0.004 - 0.034a_{t-1}^2 + 0.092a_{t-2}^2$$

The negative coefficient of a_{t-1}^2 in the prior model is counterintuitive, but the magnitude is small. As a matter of fact, for a large positive shock a_{t-1} , the ARCH effects appear to be weak even though the parameter estimates remain statistically significant.

Markov Switching Model

The idea of using probability switching in nonlinear time series analysis is discussed in Tong (1983). Using a similar idea, but emphasizing aperiodic transition between various states of an economy, Hamilton (1989) considers the Markov switching autoregressive (MSA) model. Here the transition is driven by a hidden two-state Markov chain. A time series x_t follows an MSA model if it satisfies

$$\begin{cases} c_1 + \sum_{i=1}^p \phi_{1,i} x_{t-i} + a_{1t} & \text{if } s_t = 1 \\ c_2 + \sum_{i=1}^p \phi_{2,i} x_{t-i} + a_{2t} & \text{if } s_t = 2 \end{cases} \quad (18)$$

where s_t assumes values in $\{1,2\}$ and is a first-order Markov chain with transition probabilities

$$P(s_t = 2 | s_{t-1} = 1) = w_1, \quad P(s_t = 1 | s_{t-1} = 2) = w_2$$

The innovational series $\{a_{1t}\}$ and $\{a_{2t}\}$ are sequences of IID random variables with mean zero and finite variance and are independent of one another. A small w_i means that the model tends to stay longer in state i . In fact, $1/w_i$ is the expected duration of the process to stay in state i . From the definition, an MSA model uses a hidden Markov chain to govern the transition from one conditional mean function to another. This is different from that of a SETAR model for which the transition is determined by a particular lagged variable. Consequently, a SETAR model uses a deterministic scheme to govern the model transition whereas an MSA model uses a stochastic scheme.

In practice, the stochastic nature of the states implies that one is never certain about which state x_t belongs to in an MSA model. When the sample size is large, one can use some filtering techniques to draw inference on the state of x_t . Yet as long as x_{t-d} is observed, the regime of x_t is known in a SETAR model. This difference has important practical implications in forecasting. For instance, forecasts of an MSA model are always a linear combination of forecasts produced by submodels of individual states. But those of a SETAR model only come from a single regime provided that x_{t-d} is observed.

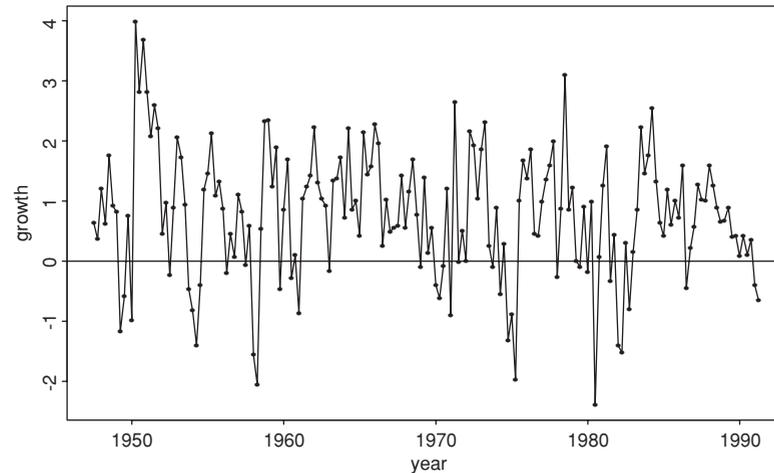

Figure 4 Time Plot of the Growth Rate of the U.S. Quarterly Real GNP from 1947.II to 1991.I
Note: The data are seasonally adjusted and in percentages.

Forecasts of a SETAR model also become a linear combination of those produced by models of individual regimes when the forecast horizon exceeds the delay d . It is much harder to estimate an MSA model than other models because the states are not directly observable. Hamilton (1990) uses the EM algorithm, which is a statistical method iterating between taking expectation and maximization. McCulloch and Tsay (1994) consider a Markov chain Monte Carlo (MCMC) method to estimate general MSA models. For applications of MCMC methods in finance, see Tsay (2010, Chapter 12).

McCulloch and Tsay (1993) generalize the MSA model in equation (18) by letting the transition probabilities w_1 and w_2 be logistic, or probit, functions of some explanatory variables available at time $t - 1$. Chen, McCulloch, and Tsay (1997) use the idea of Markov switching as a tool to perform model comparison and selection between nonnested nonlinear time series models (e.g., comparing bilinear and SETAR models). Each competing model is represented by a state. This approach to select a model is a generalization of the odds ratio commonly used in Bayesian analysis. Finally, the MSA model can easily be generalized to the case of more than two states. The computational intensity

involved increases rapidly, however. For more discussions of Markov switching models in econometrics, see Hamilton (1994, Chapter 22).

Example 5. Consider the growth rate, in percentages, of the U.S. quarterly real gross national product (GNP) from the second quarter of 1947 to the first quarter of 1991. The data are seasonally adjusted and shown in Figure 4, where a horizontal line of zero growth is also given. It is reassuring to see that a majority of the growth rates are positive. This series has been widely used in nonlinear analysis of economic time series. Tiao and Tsay (1994) and Potter (1995) use TAR models, whereas Hamilton (1989) and McCulloch and Tsay (1994) employ Markov switching models.

Employing the MSA model in equation (18) with $p = 4$ and using a Markov chain Monte Carlo method, McCulloch and Tsay (1994) obtain the estimates shown in Table 1. The results have several interesting findings. First, the mean growth rate of the marginal model for state 1 is $0.909 / (1 - 0.265 - 0.029 + 0.126 + 0.11) = 0.965$ and that of state 2 is $-0.42 / (1 - 0.216 - 0.628 + 0.073 + 0.097) = -1.288$. Thus, state 1 corresponds to quarters with positive growth, or expansion periods, whereas state 2

Table 1 Estimation Results of a Markov Switching Model with $p = 4$ for the Growth Rate of U.S. Quarterly Real GNP, Seasonally Adjusted

Parameter	State 1						
	c_i	ϕ_1	ϕ_2	ϕ_3	ϕ_4	σ_i	w_i
Estimate	0.909	0.265	0.029	-0.126	-0.110	0.816	0.118
Std. Error	0.202	0.113	0.126	0.103	0.109	0.125	0.053
Parameter	State 2						
	c_i	ϕ_1	ϕ_2	ϕ_3	ϕ_4	σ_i	w_i
Estimate	-0.420	0.216	0.628	-0.073	-0.097	1.017	0.286
Std. Error	0.324	0.347	0.377	0.364	0.404	0.293	0.064

Note: The estimates and their standard errors are posterior means and standard errors of a Gibbs sampling with 5000 iterations.

consists of quarters with negative growth, or a contraction period. Second, the relatively large posterior standard deviations of the parameters in state 2 reflect that there are few observations in that state. This is expected as Figure 4 shows few quarters with negative growth. Third, the transition probabilities appear to be different for different states. The estimates indicate that it is more likely for the U.S. GNP to get out of a contraction period than to jump into one -0.286 versus 0.118 . Fourth, treating $1/w_i$ as the expected duration for the process to stay in state i , we see that the expected durations for a contraction period and an expansion period are approximately 3.69 and 11.31 quarters. Thus, on average, a contraction in the U.S. economy lasts about a year, whereas an expansion can last for 3 years. Finally, the estimated AR coefficients of x_{t-2} differ substantially between the two states, indicating that the dynamics of the U.S. economy are different between expansion and contraction periods.

Nonparametric Methods

In some financial applications, we may not have sufficient knowledge to prespecify the nonlinear structure between two variables Y and X . In other applications, we may wish to take advantage of the advances in computing facilities and computational methods to explore the functional relationship between Y and X . These considerations lead to the use of nonparametric

methods and techniques. Nonparametric methods, however, are not without cost. They are highly data dependent and can easily result in overfitting. Our goal here is to introduce some nonparametric methods for financial applications and some nonlinear models that make use of nonparametric methods and techniques. The nonparametric methods discussed include kernel regression, local least squares estimation, and neural network.

The essence of nonparametric methods is smoothing. Consider two financial variables Y and X , which are related by

$$Y_t = m(X_t) + a_t \quad (19)$$

where $m(\cdot)$ is an arbitrary, smooth, but unknown function and $\{a_t\}$ is a white noise sequence. We wish to estimate the nonlinear function $m(\cdot)$ from the data. For simplicity, consider the problem of estimating $m(\cdot)$ at a particular date for which $X = x$. That is, we are interested in estimating $m(x)$. Suppose that at $X = x$ we have repeated independent observations y_1, \dots, y_T . Then the data become

$$y_t = m(x) + a_t, \quad t = 1, \dots, T$$

Taking the average of the data, we have

$$\frac{\sum_{t=1}^T y_t}{T} = m(x) + \frac{\sum_{t=1}^T a_t}{T}$$

By the law of large numbers, the average of the shocks converges to zero as T increases. Therefore, the average $\hat{y} = (\sum_{t=1}^T y_t)/T$ is a consistent

estimate of $m(x)$. That the average \bar{y} provides a consistent estimate of $m(x)$ or, alternatively, that the average of shocks converges to zero shows the power of smoothing.

In financial time series, we do not have repeated observations available at $X = x$. What we observed are $\{(y_t, x_t)\}$ for $t = 1, \dots, T$. But if the function $m(\cdot)$ is sufficiently smooth, then the value of Y_t for which $X_t \approx x$ continues to provide accurate approximation of $m(x)$. The value of Y_t for which X_t is far away from x provides less accurate approximation for $m(x)$. As a compromise, one can use a weighted average of y_t instead of the simple average to estimate $m(x)$. The weight should be larger for those Y_t with X_t close to x and smaller for those Y_t with X_t far away from x . Mathematically, the estimate of $m(x)$ for a given x can be written as

$$\hat{m}(x) = \frac{1}{T} \sum_{t=1}^T w_t(x) y_t \quad (20)$$

where the weights $w_t(x)$ are larger for those y_t with x_t close to x and smaller for those y_t with x_t far away from x . In equation (20), we assume that the weights sum to T . One can treat $1/T$ as part of the weights and make the weights sum to one.

From equation (20), the estimate $\hat{m}(x)$ is simply a local weighted average with weights determined by two factors. The first factor is the distance measure (i.e., the distance between x_t and x). The second factor is the assignment of weight for a given distance. Different ways to determine the distance between x_t and x and to assign the weight using the distance give rise to different nonparametric methods. In what follows, we discuss the commonly used kernel regression and local linear regression methods.

Kernel Regression

Kernel regression is perhaps the most commonly used nonparametric method in smoothing. The weights here are determined by a kernel, which is typically a probability density

function, is denoted by $K(x)$, and satisfies

$$K(x) \geq 0, \quad \int K(z) dz = 1$$

However, to increase the flexibility in distance measure, one often rescales the kernel using a variable $h > 0$, which is referred to as the bandwidth. The rescaled kernel becomes

$$K_h(x) = \frac{1}{h} K(x/h), \quad \int K_h(z) dz = 1 \quad (21)$$

The weight function can now be defined as

$$w_t(x) = \frac{K_h(x - x_t)}{\sum_{t=1}^T K_h(x - x_t)} \quad (22)$$

where the denominator is a normalization constant that makes the smoother adaptive to the local intensity of the X variable and ensures the weights sum to one. Plugging equation (22) into the smoothing formula (20), we have the well-known Nadaraya-Watson kernel estimator

$$\hat{m}(x) = \sum_{t=1}^T w_t(x) y_t = \frac{\sum_{t=1}^T K_h(x - x_t) y_t}{\sum_{t=1}^T K_h(x - x_t)} \quad (23)$$

see Nadaraya (1964) and Watson (1964). In practice, many choices are available for the kernel $K(x)$. However, theoretical and practical considerations lead to a few choices, including the Gaussian kernel

$$K_h(x) = \frac{1}{h\sqrt{2\pi}} \exp\left(-\frac{x^2}{2h^2}\right)$$

and the Epanechnikov kernel (Epanechnikov, 1969)

$$K_h(x) = \frac{0.75}{h} \left(1 - \frac{x^2}{h^2}\right) I\left(\left|\frac{x}{h}\right| \leq 1\right)$$

where $I(A)$ is an indicator such that $I(A) = 1$ if A holds and $I(A) = 0$ otherwise. Figure 5 shows the Gaussian and Epanechnikov kernels for $h = 1$.

To gain insight into the bandwidth h , we evaluate the Nadaraya-Watson estimator with the Epanechnikov kernel at the observed values $\{x_t\}$ and consider two extremes. First, if $h \rightarrow 0$, then

$$\hat{m}(x_t) \rightarrow \frac{K_h(0) y_t}{K_h(0)} = y_t$$

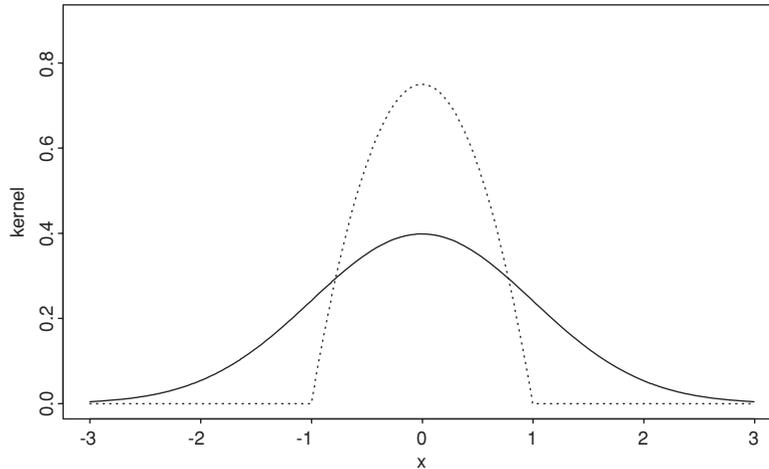

Figure 5 Standard Normal Kernel (Solid Line) and Epanechnikov Kernel (Dashed Line) with Bandwidth $h = 1$

indicating that small bandwidths reproduce the data. Second, if $h \rightarrow \infty$, then

$$\hat{m}(x_t) \rightarrow \frac{\sum_{t=1}^T K_h(0)y_t}{\sum_{t=1}^T K_h(0)} = \frac{1}{T} \sum_{t=1}^T y_t = \bar{y}$$

suggesting that large bandwidths lead to an oversmoothed curve—the sample mean. In general, the bandwidth function h acts as follows. If h is very small, then the weights focus on a few observations that are in the neighborhood around each x_t . If h is very large, then the weights will spread over a larger neighborhood of x_t . Consequently, the choice of h plays an important role in kernel regression. This is the well-known problem of bandwidth selection in kernel regression.

Bandwidth Selection

There are several approaches for bandwidth selection; see Härdle (1990) and Fan and Yao (2003). The first approach is the plug-in method, which is based on the asymptotic expansion of the mean integrated squared error (MISE) for *kernel smoothers*

$$\text{MISE} = E \int_{-\infty}^{\infty} [\hat{m}(x) - m(x)]^2 dx$$

where $m(\cdot)$ is the true function. The quantity $E[\hat{m}(x) - m(x)]^2$ of the MISE is a pointwise measure of the mean squared error (MSE) of $\hat{m}(x)$ evaluated at x .

Under some regularity conditions, one can derive the optimal bandwidth that minimizes the MISE. The optimal bandwidth typically depends on several unknown quantities that must be estimated from the data with some preliminary smoothing. Several iterations are often needed to obtain a reasonable estimate of the optimal bandwidth. In practice, the choice of preliminary smoothing can become a problem. Fan and Yao (2003) give a normal reference bandwidth selector as

$$\hat{h}_{\text{opt}} \begin{cases} 1.06sT^{-1/5} & \text{for the Gaussian kernel} \\ 2.34sT^{-1/5} & \text{for the Epanechnikov kernel} \end{cases}$$

where s is the sample standard error of the independent variable, which is assumed to be stationary.

The second approach to bandwidth selection is the leave-one-out cross-validation. First, one observation (x_j, y_j) is left out. The remaining $T - 1$ data points are used to obtain the following smoother at x_j :

$$\hat{m}_{h,j}(x_j) = \frac{1}{T-1} \sum_{t \neq j} w_t(x_j)y_t$$

which is an estimate of y_j , where the weights $w_t(x_j)$ sum to $T-1$. Second, perform step-1 for $j = 1, \dots, T$ and define the function

$$CV(h) = \frac{1}{T} \sum_{j=1}^T [y_j - \hat{m}_{h,j}(x_j)]^2 W(x_j)$$

where $w(\cdot)$ is a nonnegative weight function satisfying $\sum_{j=1}^n W(x_j) = T$, that can be used to down-weight the boundary points if necessary. Decreasing the weights assigned to data points close to the boundary is needed because those points often have fewer neighboring observations. The function $CV(h)$ is called the cross-validation function because it validates the ability of the smoother to predict $\{y_t\}_{t=1}^T$. One chooses the bandwidth h that minimizes the $CV(\cdot)$ function.

Local Linear Regression Method

Assume that the second derivative of $m(\cdot)$ in model (19) exists and is continuous at x , where x is a given point in the support of $m(\cdot)$. Denote the data available by $\{(y_t, x_t)\}_{t=1}^T$. The *local linear regression* method to nonparametric regression is to find a and b that minimize

$$L(a, b) = \sum_{t=1}^T [y_t - a - b(x - x_t)]^2 K_h(x - x_t) \quad (24)$$

where $K_h(\cdot)$ is a kernel function defined in equation (21) and h is a bandwidth. Denote the resulting value of a by \hat{a} . The estimate of $m(x)$ is then defined as \hat{a} . In practice, x assumes an observed value of the independent variable. The estimate \hat{b} can be used as an estimate of the first derivative of $m(\cdot)$ evaluated at x .

Under the least squares theory, equation (24) is a weighted least squares problem and one can derive a closed-form solution for a . Specifically, taking the partial derivatives of $L(a, b)$ with respect to both a and b and equating the derivatives to zero, we have a system of two equations with two unknowns:

$$\begin{aligned} \sum_{t=1}^T K_h(x - x_t) y_t &= a \sum_{t=1}^T K_h(x - x_t) \\ &+ b \sum_{t=1}^T (x - x_t) K_h(x - x_t) \end{aligned}$$

$$\begin{aligned} \sum_{t=1}^T y_t (x - x_t) K_h(x - x_t) &= a \sum_{t=1}^T (x - x_t) K_h(x - x_t) \\ &+ b \sum_{t=1}^T (x - x_t)^2 K_h(x - x_t) \end{aligned}$$

Define

$$s_{T,\ell} = \sum_{t=1}^T K_h(x - x_t) (x - x_t)^\ell, \quad \ell = 0, 1, 2.$$

The prior system of equations becomes

$$\begin{aligned} \begin{bmatrix} s_{T,0} & s_{T,1} \\ s_{T,1} & s_{T,2} \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} \\ = \begin{bmatrix} \sum_{t=1}^T K_h(x - x_t) y_t \\ \sum_{t=1}^T (x - x_t) K_h(x - x_t) y_t \end{bmatrix} \end{aligned}$$

Consequently, we have

$$\hat{a} = \frac{s_{T,2} \sum_{t=1}^T K_h(x - x_t) y_t - s_{T,1} \sum_{t=1}^T (x - x_t) K_h(x - x_t) y_t}{s_{T,0} s_{T,2} - s_{T,1}^2}$$

The numerator and denominator of the prior fraction can be further simplified as

$$\begin{aligned} s_{T,2} &= \sum_{t=1}^T K_h(x - x_t) y_t \\ &\quad - s_{T,1} \sum_{t=1}^T (x - x_t) K_h(x - x_t) y_t \\ &= \sum_{t=1}^T [K_h(x - x_t) (s_{T,2} - (x - x_t) s_{T,1})] y_t \\ s_{T,0} s_{T,2} - s_{T,1}^2 &= \sum_{t=1}^T K_h(x - x_t) s_{T,2} \\ &\quad - \sum_{t=1}^T (x - x_t) K_h(x - x_t) s_{T,1} \\ &= \sum_{t=1}^T K_h(x - x_t) [(s_{T,2} - (x - x_t) s_{T,1})] \end{aligned}$$

In summary, we have

$$\hat{a} = \frac{\sum_{t=1}^T w_t y_t}{\sum_{t=1}^T w_t} \quad (25)$$

where w_t is defined as

$$w_t = K_h(x - x_t) [s_{T,2} - (x - x_t) s_{T,1}]$$

In practice, to avoid possible zero in the denominator, we use $\hat{m}(x)$ next to estimate $m(x)$:

$$\hat{m}(x) = \frac{\sum_{t=1}^T w_t y_t}{\sum_{t=1}^T w_t + 1/T^2} \quad (26)$$

Notice that a nice feature of equation (26) is that the weight w_t satisfies

$$\sum_{t=1}^T (x - x_t)w_t = 0$$

Also, if one assumes that $m(\cdot)$ of equation (19) has the first derivative and finds the minimizer of

$$\sum_{t=1}^T (y_t - a)^2 K_h(x - x_t)$$

then the resulting estimator is the Nadaraya-Watson estimator mentioned earlier. In general, if one assumes that $m(x)$ has a bounded k th derivative, then one can replace the linear polynomial in equation (24) by a $(k - 1)$ -order polynomial. We refer to the estimator in equation (26) as the local linear regression smoother. Fan (1993) shows that, under some regularity conditions, the local linear regression estimator has some important sampling properties. The selection of bandwidth can be carried out via the same methods as before.

Financial Time Series Application

In time series analysis, the explanatory variables are often the lagged values of the series. Consider the simple case of a single explanatory variable. Here model (19) becomes

$$x_t = m(x_{t-1}) + a_t$$

and the kernel regression and local linear regression method discussed before are directly applicable. When multiple explanatory variables exist, some modifications are needed to implement the nonparametric methods. For the kernel regression, one can use a multivariate kernel such as a multivariate normal density function with a prespecified covariance matrix:

$$K_h(\mathbf{x}) = \frac{1}{(h\sqrt{2\pi})^p |\Sigma|^{1/2}} \exp\left(-\frac{1}{2h^2} \mathbf{x}' \Sigma^{-1} \mathbf{x}\right)$$

where p is the number of explanatory variables and Σ is a prespecified positive-definite matrix. Alternatively, one can use the product of

univariate kernel functions as a multivariate kernel—for example,

$$K_h(\mathbf{x}) = \prod_{i=1}^p \frac{0.75}{h_i} \left(1 - \frac{x_i^2}{h_i^2}\right) I\left(\left|\frac{x_i}{h_i}\right| < 1\right)$$

This latter approach is simple, but it overlooks the relationship between the explanatory variables.

Example 6. To illustrate the application of nonparametric methods in finance, consider the weekly 3-month Treasury bill secondary market rate from 1970 to 1997 for 1,461 observations. The data are obtained from the Federal Reserve Bank of St. Louis and are shown in Figure 6. This series has been used in the literature as an example of estimating stochastic diffusion equations using discretely observed data. Here we consider a simple model

$$y_t = \mu(x_{t-1})dt + \sigma(x_{t-1})dw_t$$

where x_t is the 3-month Treasury bill rate, $y_t = x_t - x_{t-1}$, w_t is a standard Brownian motion, and $\mu(\cdot)$ and $\sigma(\cdot)$ are smooth functions of x_{t-1} , and apply the local smoothing function *lowess* of R or S-Plus to obtain nonparametric estimates of $\mu(\cdot)$ and $\sigma(\cdot)$; see Cleveland (1979). For simplicity, we use $|y_t|$ as a proxy of the volatility of x_t .

For the simple model considered, $\mu(x_{t-1})$ is the conditional mean of y_t given x_{t-1} , that is, $\mu(x_{t-1}) = E(y_t|x_{t-1})$. Figure 7(a) shows the scatterplot of $y(t)$ versus x_{t-1} . The plot also contains the local smooth estimate of $\mu(x_{t-1})$ obtained by the method of *lowess* in the statistical package R. The estimate is essentially zero. However, to better understand the estimate, Figure 7(b) shows the estimate $\hat{\mu}(x_{t-1})$ on a finer scale. It is interesting to see that $\hat{\mu}(x_{t-1})$ is positive when x_{t-1} is small, but becomes negative when x_{t-1} is large. This is in agreement with the common sense that when the interest rate is high, it is expected to come down, and when the rate is low, it is expected to increase. Figure 7(c) shows the scatterplot of $|y(t)|$ versus x_{t-1} and the estimate of $\hat{\sigma}(x_{t-1})$ via *lowess*. The plot confirms that the

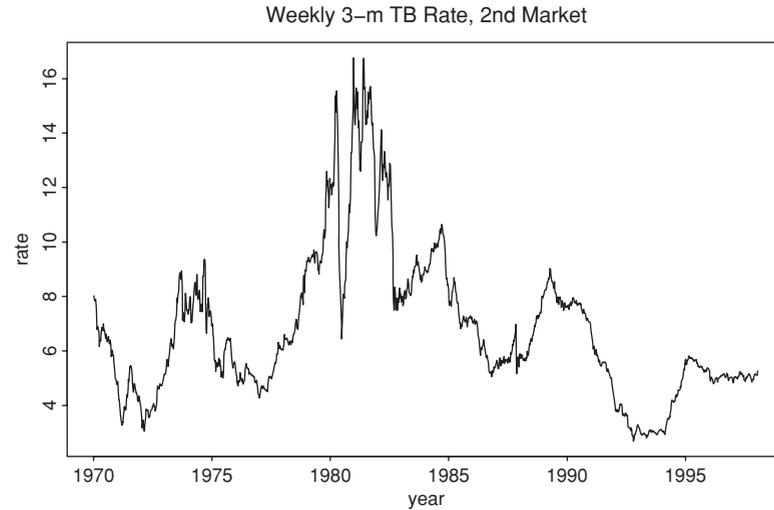

Figure 6 Time Plot of U.S. Weekly 3-Month Treasury Bill Rate in the Secondary Market from 1970 to 1997

higher the interest rate, the larger the volatility. Figure 7(d) shows the estimate $\hat{\sigma}(x_{t-1})$ on a finer scale. Clearly the volatility is an increasing function of x_{t-1} and the slope seems to accelerate when x_{t-1} is approaching 10%. This exam-

ple demonstrates that simple non-parametric methods can be helpful in understanding the dynamic structure of a financial time series.

The following nonlinear models are derived with the help of nonparametric methods.

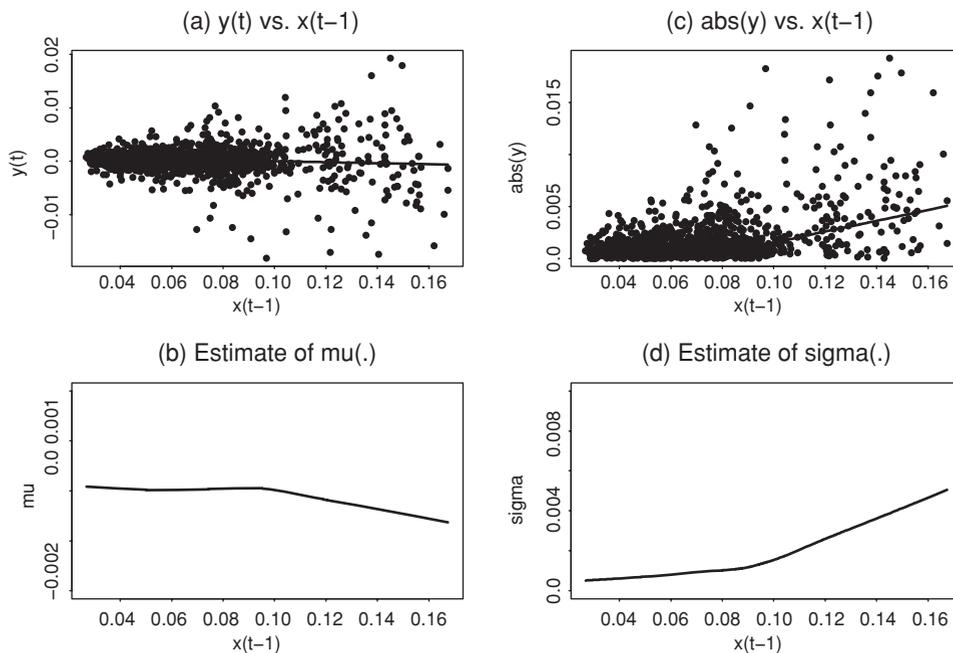

Figure 7 Estimation of Conditional Mean and Volatility of Weekly 3-Month Treasury Bill Rate via a Local Smoothing Method: (a) y_t versus x_{t-1} , where $y_t = x_t - x_{t-1}$ and x_t is the interest rate; (b) estimate of $\mu(x_{t-1})$; (c) $|y_t|$ versus x_{t-1} ; and (d) estimate of $\sigma(x_{t-1})$

Functional Coefficient AR Model

Recent advances in nonparametric techniques enable researchers to relax parametric constraints in proposing nonlinear models. In some cases, nonparametric methods are used in a preliminary study to help select a parametric nonlinear model. This is the approach taken by Chen and Tsay (1993a) in proposing the functional-coefficient autoregressive (FAR) model that can be written as

$$x_t = f_1(X_{t-1})x_{t-1} + \cdots + f_p(X_{t-1})x_{t-p} + a_t \quad (27)$$

where $X_{t-1} = (x_{t-1}, \dots, X_{t-k})'$ is a vector of lagged values of x_t . If necessary x_{t-1} may also include other explanatory variables available at time $t-1$. The functions $f_i(\cdot)$ of equation (27) are assumed to be continuous, even twice differentiable, almost surely with respect to their arguments. Most of the nonlinear models discussed before are special cases of the FAR model. In application, one can use nonparametric methods such as kernel regression or local linear regression to estimate the functional coefficients $f_i(\cdot)$, especially when the dimension of X_{t-1} is low (e.g., X_{t-1} is a scalar). Recently, Cai, Fan, and Yao (2000) applied the local linear regression method to estimate $f_i(\cdot)$ and showed that substantial improvements in 1-step ahead forecasts can be achieved by using FAR models.

Nonlinear Additive AR Model

A major difficulty in applying nonparametric methods to nonlinear time series analysis is the "curse of dimensionality." Consider a general nonlinear AR(p) process $x_t = f(x_{t-1}, \dots, x_{t-p}) + a_t$. A direct application of nonparametric methods to estimate $f(\cdot)$ would require p -dimensional smoothing, which is hard to do when p is large, especially if the number of data points is not large. A simple, yet effective way to overcome this difficulty is to entertain an additive model that only requires lower dimensional smoothing. A time series x_t follows a nonlinear

additive AR (NAAR) model if

$$x_t = f_0(t) + \sum_{i=1}^p f_i(x_{t-i}) + a_t \quad (28)$$

where the $f_i(\cdot)$ are continuous functions almost surely. Because each function $f_i(\cdot)$ has a single argument, it can be estimated nonparametrically using one-dimensional smoothing techniques and hence avoids the curse of dimensionality. In application, an iterative estimation method that estimates $f_i(\cdot)$ nonparametrically conditioned on estimates of $f_j(\cdot)$ for all $j \neq i$ is used to estimate a NAAR model; see Chen and Tsay (1993b) for further details and examples of NAAR models.

The additivity assumption is rather restrictive and needs to be examined carefully in application. Chen, Liu, and Tsay (1995) consider test statistics for checking the additivity assumption.

Nonlinear State-Space Model

Making use of recent advances in MCMC methods (Gelfand and Smith, 1990), Carlin, Polson, and Stoffer (1992) propose a Monte Carlo approach for nonlinear state-space modeling. The model considered is

$$S_t = f_t(S_{t-1}) + u_t, \quad x_t = g_t(S_t) + v_t \quad (29)$$

where S_t is the state vector, $f_t(\cdot)$ and $g_t(\cdot)$ are known functions depending on some unknown parameters, $\{u_t\}$ is a sequence of IID multivariate random vectors with zero mean and non-negative definite covariance matrix Σu , $\{v_t\}$ is a sequence of IID random variables with mean zero and variance σ_v^2 , and $\{u_t\}$ is independent of $\{v_t\}$.

Monte Carlo techniques are employed to handle the nonlinear evolution of the state transition equation because the whole conditional distribution function of S_t given S_{t-1} is needed for a nonlinear system. Other numerical smoothing methods for nonlinear time series analysis have been considered by Kitagawa

(1998) and the references therein. MCMC methods (or computing-intensive numerical methods) are powerful tools for nonlinear time series analysis. Their potential has not been fully explored. However, the assumption of knowing $f_i(\cdot)$ and $g_i(\cdot)$ in model (29) may hinder practical use of the proposed method. A possible solution to overcome this limitation is to use nonparametric methods such as the analyses considered in FAR and NAAR models to specify $f_i(\cdot)$ and $g_i(\cdot)$ before using nonlinear state-space models.

Neural Networks

A popular topic in modern data analysis is neural network, which can be classified as a semiparametric method. The literature on neural network is enormous, and its application spreads over many scientific areas with varying degrees of success; see Ripley (1993, Sections 2 and 10). Cheng and Titterton (1994) provide information on neural networks from a statistical viewpoint. In this subsection, we focus solely on the feed-forward neural networks in which inputs are connected to one or more neurons, or nodes, in the input layer, and these nodes are connected forward to further layers until they reach the output layer. Figure 8 shows an example of a simple feed-forward network for univariate time series analysis with one hidden layer. The input layer has two nodes, and the hidden layer has three. The input nodes are connected forward to each and every node in the hidden layer, and these hidden nodes

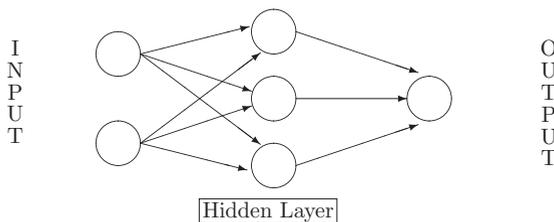

Figure 8 A Feed-Forward Neural Network with One Hidden Layer for Univariate Time Series Analysis

are connected to the single node in the output layer. We call the network a 2-3-1 feed-forward network. More complicated neural networks, including those with feedback connections, have been proposed in the literature, but the feed-forward networks are most relevant to our study.

Feed-Forward Neural Networks

A neural network processes information from one layer to the next by an “activation function.” Consider a feed-forward network with one hidden layer. The j th node in the hidden layer is defined as

$$h_j = f_j(\alpha_{0j} + \sum_{i \rightarrow j} w_{ij}x_i) \quad (30)$$

where x_i is the value of the i th input node, $f_j(\cdot)$ is an activation function typically taken to be the logistic function

$$f_j(z) = \frac{\exp(z)}{1 + \exp(z)}$$

α_{0j} is called the bias, the summation $i \rightarrow j$ means summing over all input nodes feeding to j , and w_{ij} are the weights. For illustration, the j th node of the hidden layer of the 2-3-1 feed-forward network in Figure 8 is

$$h_j = \frac{\exp(\alpha_{0j} + w_{1j}x_1 + w_{2j}x_2)}{1 + \exp(\alpha_{0j} + w_{1j}x_1 + w_{2j}x_2)}, \quad j = 1, 2, 3. \quad (31)$$

For the output layer, the node is defined as

$$o = f_o(\alpha_{0o} + \sum_{j \rightarrow o} w_{jo}h_j) \quad (32)$$

where the activation function $f_o(\cdot)$ is either linear or a Heaviside function. If $f_o(\cdot)$ is linear, then

$$o = \alpha_{0o} + \sum_{j=1}^k w_{jo}h_j$$

where k is the number of nodes in the hidden layer. By a Heaviside function, we mean $f_o(z) = 1$ if $z > 0$ and $f_o(z) = 0$ otherwise. A neuron with a Heaviside function is called a threshold neuron, with “1” denoting that the neuron fires its message. For example, the output of the

2-3-1 network in Figure 8 is

$$o = \alpha_{0o} + w_{1o}h_1 + w_{2o}h_2 + w_{3o}h_3$$

if the activation function is linear; it is

$$o = \begin{cases} 1 & \text{if } \alpha_{0o} + w_{1o}h_1 + w_{2o}h_2 + w_{3o}h_3 > 0 \\ 0 & \text{if } \alpha_{0o} + w_{1o}h_1 + w_{2o}h_2 + w_{3o}h_3 \leq 0 \end{cases}$$

if $f_o(\cdot)$ is a Heaviside function.

Combining the layers, the output of a feed-forward neural network can be written as

$$o = f_o \left[\alpha_{0o} + \sum_{j \rightarrow o} w_{jo} f_j \left(\alpha_{0j} + \sum_{i \rightarrow j} w_{ij} x_i \right) \right] \quad (33)$$

If one also allows for direct connections from the input layer to the output layer, then the network becomes

$$o = f_o \left[\alpha_{0o} + \sum_{i \rightarrow o} \alpha_{io} x_i + \sum_{j \rightarrow o} w_{jo} f_j \left(\alpha_{0j} + \sum_{i \rightarrow j} w_{ij} x_i \right) \right] \quad (34)$$

where the first summation is summing over the input nodes. When the activation function of the output layer is linear, the direct connections from the input nodes to the output node represent a linear function between the inputs and output. Consequently, in this particular case model (34) is a generalization of linear models. For the 2-3-1 network in Figure 8, if the output activation function is linear, then equation (33) becomes

$$o = \alpha_{0o} + \sum_{j=1}^3 w_{jo} h_j$$

where h_j is given in equation (31). The network thus has 13 parameters. If equation (34) is used, then the network becomes

$$o = \alpha_{0o} + \sum_{i=1}^2 \alpha_{io} x_i + \sum_{j=1}^3 w_{jo} h_j$$

where again h_j is given in equation (31). The number of parameters of the network increases to 15.

We refer to the function in equation (33) or (34) as a semiparametric function because its func-

tional form is known, but the number of nodes and their biases and weights are unknown. The direct connections from the input layer to the output layer in equation (34) mean that the network can skip the hidden layer. We refer to such a network as a skip-layer feed-forward network.

Feed-forward networks are known as multilayer perceptrons in the neural network literature. They can approximate any continuous function uniformly on compact sets by increasing the number of nodes in the hidden layer; see Hornik, Stinchcombe, and White (1989), Hornik (1993), and Chen and Chen (1995). This property of neural networks is the universal approximation property of the multilayer perceptrons. In short, feed-forward neural networks with a hidden layer can be seen as a way to parameterize a general continuous nonlinear function.

Training and Forecasting

Application of neural networks involves two steps. The first step is to train the network (i.e., to build a network, including determining the number of nodes and estimating their biases and weights). The second step is inference, especially forecasting. The data are often divided into two nonoverlapping subsamples in the training stage. The first subsample is used to estimate the parameters of a given feed-forward neural network. The network so built is then used in the second subsample to perform forecasting and compute its forecasting accuracy. By comparing the forecasting performance, one selects the network that outperforms the others as the "best" network for making inference. This is the idea of cross-validation widely used in statistical model selection. Other model selection methods are also available.

In a time series application, let $\{(r_t, \mathbf{x}_t) | t = 1, \dots, T\}$ be the available data for network training, where \mathbf{x}_t denotes the vector of inputs and r_t is the series of interest (e.g., log returns of an asset). For a given network, let o_t be the output of the network with input \mathbf{x}_t ; see equation (34). Training a neural network amounts to choosing

its biases and weights to minimize some fitting criterion—for example, the least squares

$$S^2 = \sum_{t=1}^T (r_t - o_t)^2$$

This is a nonlinear estimation problem that can be solved by several iterative methods. To ensure the smoothness of the fitted function, some additional constraints can be added to the prior minimization problem. In the neural network literature, the back propagation (BP) learning algorithm is a popular method for network training. The BP method, introduced by Bryson and Ho (1969), works backward starting with the output layer and uses a gradient rule to modify the biases and weights iteratively. (Appendix 2A of Ripley, 1993, provides a derivation of back propagation.) Once a feed-forward neural network is built, it can be used to compute forecasts in the forecasting subsample.

Example 7. To illustrate applications of the neural network in finance, we consider the monthly log returns, in percentages and including dividends, for IBM stock from January 1926 to December 1999. We divide the data into two subsamples. The first subsample consisting of returns from January 1926 to December 1997 for 864 observations is used for modeling. Using model (34) with three inputs and two nodes in the hidden layer, we obtain a 3-2-1 network for the series. The three inputs are r_{t-1} , r_{t-2} , and r_{t-3} and the biases and weights are given next:

$$\hat{r}_t = 3.22 - 1.81f_1(r_{t-1}) - 2.28f_2(r_{t-1}) - 0.09r_{t-1} - 0.05r_{t-2} - 0.12r_{t-3} \quad (35)$$

where $r_{t-1} = (r_{t-1}, r_{t-2}, r_{t-3})$ and the two logistic functions are

$$f_1(r_{t-1}) = \frac{\exp(-8.34 - 18.97r_{t-1} + 2.17r_{t-2} - 19.17r_{t-3})}{1 + \exp(-8.34 - 18.97r_{t-1} + 2.17r_{t-2} - 19.17r_{t-3})}$$

$$f_2(r_{t-1}) = \frac{\exp(39.25 - 22.17r_{t-1} - 17.34r_{t-2} - 5.98r_{t-3})}{1 + \exp(39.25 - 22.17r_{t-1} - 17.34r_{t-2} - 5.98r_{t-3})}$$

The standard error of the residuals for the prior model is 6.56. For comparison, we also built an AR model for the data and obtained

$$r_t = 1.101 + 0.077r_{t-1} + a_t, \quad \sigma_a = 6.61 \quad (36)$$

The residual standard error is slightly greater than that of the feed-forward model in equation (35).

Forecast Comparison

The monthly returns of IBM stock in 1998 and 1999 form the second subsample and are used to evaluate the out-of-sample forecasting performance of neural networks. As a benchmark for comparison, we use the sample mean of r_t in the first subsample as the 1-step ahead forecast for all the monthly returns in the second subsample. This corresponds to assuming that the log monthly price of IBM stock follows a random walk with drift. The mean squared forecast error (MSFE) of this benchmark model is 91.85. For the AR(1) model in equation (36), the MSFE of 1-step ahead forecasts is 91.70. Thus, the AR(1) model slightly outperforms the benchmark. For the 3-2-1 feed-forward network in equation (35), the MSFE is 91.74, which is essentially the same as that of the AR(1) model.

Example 8. Nice features of the feed-forward network include its flexibility and wide applicability. For illustration, we use the network with a Heaviside activation function for the output layer to forecast the direction of price movement for IBM stock considered in Example 7. Define a direction variable as

$$d_t = \begin{cases} 1 & \text{if } r_t \geq 0 \\ 0 & \text{if } r_t < 0 \end{cases}$$

We use eight input nodes consisting of the first four lagged values of both r_t and d_t and four nodes in the hidden layer to build an 8-4-1 feed-forward network for d_t in the first subsample. The resulting network is then used to compute the 1-step ahead probability of an “upward movement” (i.e., a positive return) for the following month in the second subsample.

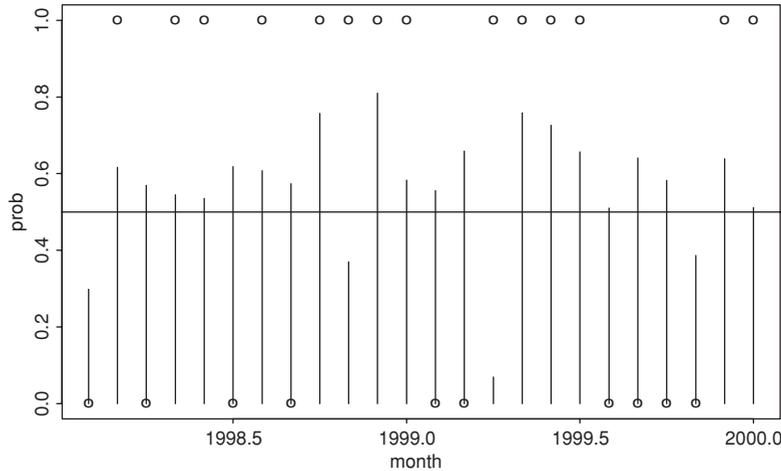

Figure 9 One-Step Ahead Probability Forecasts for a Positive Monthly Return for IBM Stock Using an 8-4-1 Feed-Forward Neural Network

Note: The forecasting period is from January 1998 to December 1999.

Figure 9 shows a typical output of probability forecasts and the actual directions in the second subsample with the latter denoted by circles. A horizontal line of 0.5 is added to the plot. If we take a rigid approach by letting $\hat{d}_t = 1$ if the probability forecast is greater than or equal to 0.5 and $\hat{d}_t = 0$ otherwise, then the neural network has a successful rate of 0.58. The success rate of the network varies substantially from one estimation to another, and the network uses 49 parameters.

To gain more insight, we did a simulation study of running the 8-4-1 feed-forward network 500 times and computed the number of errors in predicting the upward and downward movement using the same method as before. The mean and median of errors over the 500 runs are 11.28 and 11, respectively, whereas the maximum and minimum number of errors are 18 and 4. For comparison, we also did a simulation with 500 runs using a random walk with drift—that is,

$$\hat{d}_t = \begin{cases} 1 & \text{if } \hat{r}_t = 1.19 + \epsilon_t \geq 0, \\ 0 & \text{otherwise} \end{cases}$$

where 1.19 is the average monthly log return for IBM stock from January 1926 to December

1997 and $\{\epsilon_t\}$ is a sequence of IID $N(0,1)$ random variables. The mean and median of the number of forecast errors become 10.53 and 11, whereas the maximum and minimum number of errors are 17 and 5, respectively. Figure 10 shows the histograms of the number of forecast errors for the two simulations. The results show that the 8-4-1 feed-forward neural network does not outperform the simple model that assumes a random walk with drift for the monthly log price of IBM stock.

NONLINEARITY TESTS

In this section, we discuss some nonlinearity tests available in the literature that have decent power against the nonlinear models considered earlier in this entry. The tests discussed include both parametric and nonparametric statistics. The Ljung-Box statistics of squared residuals, the bispectral test, and the Brock, Dechert, and Scheinkman (BDS) test are nonparametric methods. The *RESET test* (Ramsey, 1969), the *F tests* of Tsay (1986, 1989), and other Lagrange multiplier and likelihood ratio tests depend on specific parametric functions. Because nonlinearity may occur in many ways, there exists no

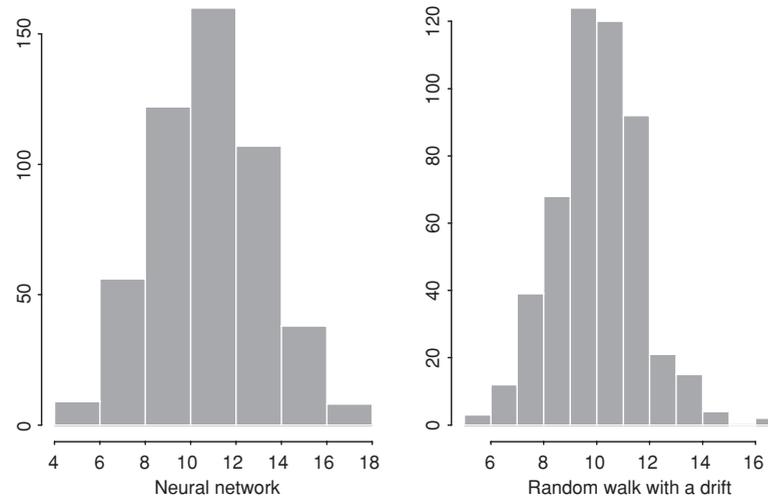

Figure 10 Histograms of the Number of Forecasting Errors for the Directional Movements of Monthly Log Returns of IBM Stock

Note: The forecasting period is from January 1998 to December 1999.

single test that dominates the others in detecting nonlinearity.

Nonparametric Tests

Under the null hypothesis of linearity, residuals of a properly specified linear model should be independent. Any violation of independence in the residuals indicates inadequacy of the entertained model, including the linearity assumption. This is the basic idea behind various nonlinearity tests. In particular, some of the nonlinearity tests are designed to check for possible violation in quadratic forms of the underlying time series.

Q-Statistic of Squared Residuals

McLeod and Li (1983) apply the Ljung-Box statistics to the squared residuals of an ARMA(p, q) model to check for model inadequacy. The test statistic is

$$Q(m) = T(T + 2) \sum_{i=1}^m \frac{\hat{\rho}_i^2(a_t^2)}{T - i}$$

where T is the sample size, m is a properly chosen number of autocorrelations used in the test,

a_t denotes the residual series, and $\hat{\rho}_i(a_t^2)$ is the lag- i ACF of a_t^2 . If the entertained linear model is adequate, $Q(m)$ is asymptotically a chi-squared random variable with $m - p - q$ degrees of freedom. The prior Q -statistic is useful in detecting conditional heteroscedasticity of a_t and is asymptotically equivalent to the Lagrange multiplier test statistic of Engle (1982) for ARCH models. The null hypothesis of the statistics is $H_0: \beta_1 = \dots = \beta_m = 0$, where β_i is the coefficient of a_{t-i}^2 in the linear regression

$$a_t^2 = \beta_0 + \beta_1 a_{t-1}^2 + \dots + \beta_m a_{t-m}^2 + e_t$$

for $t = m + 1, \dots, T$. Because the statistic is computed from residuals (not directly from the observed returns), the number of degrees of freedom is $m - p - q$.

Bispectral Test

This test can be used to test for linearity and Gaussianity. It depends on the result that a properly normalized bispectrum of a linear time series is constant over all frequencies and that the constant is zero under normality. The bispectrum of a time series is the Fourier transform of its third-order moments. For a

stationary time series x_t in equation (1), the third-order moment is defined as

$$c(u, v) = g \sum_{k=-\infty}^{\infty} \psi_k \psi_{k+u} \psi_{k+v} \quad (37)$$

where u and v are integers, $g = E(a_t^3)$, $\psi_0 = 1$, and $\psi_k = 0$ for $k < 0$. Taking Fourier transforms of equation (37), we have

$$b_3(w_1, w_2) = \frac{g}{4\pi^2} \Gamma[-(w_1 + w_2)] \Gamma(w_1) \Gamma(w_2) \quad (38)$$

where $\Gamma(w) = \sum_{u=0}^{\infty} \psi_u \exp(-i w u)$ with $i = \sqrt{-1}$, and w_i are frequencies. Yet the spectral density function of x_t is given by

$$p(w) = \frac{\sigma_a^2}{2\pi} |\Gamma(w)|^2$$

where w denotes the frequency. Consequently, the function

$$b(w_1, w_2) = \frac{|b_3(w_1, w_2)|^2}{p(w_1)p(w_2)p(w_1 + w_2)} \quad (39)$$

= constant for all (w_1, w_2)

The bispectrum test makes use of the property in equation (39). Basically, it estimates the function $b(w_1, w_2)$ in equation (39) over a suitably chosen grid of points and applies a test statistic similar to Hotelling's T^2 statistic to check the constancy of $b(w_1, w_2)$. For a linear Gaussian series, $E(a_t^3) = g = 0$ so that the bispectrum is zero for all frequencies (w_1, w_2) . For further details of the bispectral test, see Priestley (1988), Subba Rao and Gabr (1984), and Hinich (1982). Limited experience shows that the test has decent power when the sample size is large.

BDS Statistic

Brock, Dechert, and Scheinkman (1987) propose a test statistic, commonly referred to as the *BDS test*, to detect the IID assumption of a time series. The statistic is, therefore, different from other test statistics discussed because the latter mainly focus on either the second- or third-order properties of x_t . The basic idea of the BDS test is to make use of a "correlation integral"

popular in chaotic time series analysis. Given a k -dimensional time series X_t and observations $\{X_t\}_{t=1}^{T_k}$, define the correlation integral as

$$C_k(\delta) = \lim_{T_k \rightarrow \infty} \frac{2}{T_k(T_k - 1)} \sum_{i < j} I_\delta(X_i, X_j) \quad (40)$$

where $I_\delta(u, v)$ is an indicator variable that equals one if $\|u - v\| < \delta$, and zero otherwise, where $\|\cdot\|$ is the supnorm. The correlation integral measures the fraction of data pairs of $\{X_t\}$ that are within a distance of δ from each other.

Consider next a time series x_t . Construct k -dimensional vectors $X_t^k = (x_t, x_{t+1}, \dots, x_{t+k-1})'$, which are called k -histories. The idea of the BDS test is as follows. Treat a k -history as a point in the k -dimensional space. If $\{x_t\}_{t=1}^T$ are indeed IID random variables, then the k -histories $\{X_t^k\}_{t=1}^{T_k}$ should show no pattern in the k -dimensional space. Consequently, the correlation integrals should satisfy the relation $C_k(\delta) = [C_1(\delta)]^k$. Any departure from the prior relation suggests that x_t are not IID. As a simple but informative example, consider a sequence of IID random variables from the uniform distribution over $[0, 1]$. Let $[a, b]$ be a subinterval of $[0, 1]$ and consider the "2-history" (x_t, x_{t+1}) , which represents a point in the two-dimensional space. Under the IID assumption, the expected number of 2-histories in the subspace $[a, b] \times [a, b]$ should equal the square of the expected number of x_t in $[a, b]$.

This idea can be formally examined by using sample counterparts of correlation integrals. Define

$$C_\ell(\delta, T) = \frac{2}{T_\ell(T_\ell - 1)} \sum_{i < j} I_\delta(X_i^*, X_j^*), \quad \ell = 1, k$$

where $T_\ell = T - \ell + 1$ and $X_i^* = x_i$ if $\ell = 1$ and $X_i^* = X_i^k$ if $\ell = k$. Under the null hypothesis that $\{x_t\}$ are IID with a nondegenerated distribution function $F(\cdot)$, Brock, Dechert, and Scheinkman (1987) show that

$$C_k(\delta, T) \rightarrow [C_1(\delta)]^k \quad \text{with probability 1,} \\ \text{as } T \rightarrow \infty$$

for any fixed k and δ . Furthermore, the statistic $\sqrt{T}\{C_k(\delta, T) - [C_1(\delta, T)]^k\}$ is asymptotically distributed as normal with mean zero and variance

$$\sigma_k^2(\delta) = 4 \left(N^k + 2 \sum_{j=1}^{k-1} N^{k-j} C^{2j} + (k-1)^2 C^{2k} - k^2 N C^{2k-2} \right)$$

where $C = \int [F(z + \delta) - F(z - \delta)] dF(z)$ and $N = \int [F(z + \delta) - F(z - \delta)]^2 dF(z)$. Note that $C_1\{\delta, T\}$ is a consistent estimate of C , and N can be consistently estimated by

$$N(\delta, T) = \frac{6}{T_k(T_k - 1)(T_k - 2)} \sum_{t < s < u} I_\delta(x_t, x_s) I_\delta(x_s, x_u)$$

The BDS test statistic is then defined as

$$D_k(\delta, T) = \sqrt{T} \{C_k(\delta, T) - [C_1(\delta, T)]^k\} / \sigma_k(\delta, T) \quad (41)$$

where $\sigma_k(\delta, T)$ is obtained from $\sigma_k(\delta)$ when C and N are replaced by $C_1(\delta, T)$ and $N(\delta, T)$, respectively. This test statistic has a standard normal limiting distribution. For further discussion and examples of applying the BDS test, see Hsieh (1989) and Brock, Hsieh, and LeBaron (1991). In application, one should remove linear dependence, if any, from the data before applying the BDS test. The test may be sensitive to the choices of δ and k , especially when k is large.

Parametric Tests

Turning to parametric tests, we consider the RESET test of Ramsey (1969) and its generalizations. We also discuss some test statistics for detecting threshold nonlinearity.

The RESET Test

Ramsey (1969) proposes a specification test for linear least squares regression analysis. The test is referred to as a RESET test and is readily applicable to linear AR models. Consider the linear AR(p) model

$$x_t = \mathbf{X}'_{t-1} \boldsymbol{\phi} + a_t \quad (42)$$

where $\mathbf{X}_{t-1} = (1, x_{t-1}, \dots, x_{t-p})'$ and $\boldsymbol{\phi} = (\phi_0, \phi_1, \dots, \phi_p)'$. The first step of the RESET test is to obtain the least squares estimate $\hat{\boldsymbol{\phi}}$ of equation (42) and compute the fit $\hat{x}_t = \mathbf{X}'_{t-1} \hat{\boldsymbol{\phi}}$, the residual $\hat{a}_t = x_t - \hat{x}_t$, and the sum of squared residuals $SSR_0 = \sum_{t=p+1}^T \hat{a}_t^2$, where T is the sample size. In the second step, consider the linear regression

$$\hat{a}_t = \mathbf{X}'_{t-1} \boldsymbol{\alpha}_1 + \mathbf{M}'_{t-1} \boldsymbol{\alpha}_2 + v_t \quad (43)$$

where $\mathbf{M}_{t-1} = (\hat{x}_t^2, \dots, \hat{x}_t^{s+1})'$ for some $s \geq 1$, and compute the least squares residuals

$$\hat{v}_t = \hat{a}_t - \mathbf{X}'_{t-1} \hat{\boldsymbol{\alpha}}_1 - \mathbf{M}'_{t-1} \hat{\boldsymbol{\alpha}}_2$$

and the sum of squared residuals $SSR_1 = \sum_{t=p+1}^T \hat{v}_t^2$ of the regression. The basic idea of the RESET test is that if the linear AR(p) model in equation (42) is adequate, then $\boldsymbol{\alpha}_1$ and $\boldsymbol{\alpha}_2$ of equation (43) should be zero. This can be tested by the usual F statistic of equation (43) given by

$$F = \frac{(SSR_0 - SSR_1)/g}{SSR_1/(T - p - g)} \quad \text{with} \quad g = s + p + 1 \quad (44)$$

which, under the linearity and normality assumption, has an F distribution with degrees of freedom g and $T - p - g$.

Because \hat{x}_t^k for $k = 2, \dots, s + 1$ tend to be highly correlated with \mathbf{X}_{t-1} and among themselves, principal components of \mathbf{M}_{t-1} that are not colinear with \mathbf{X}_{t-1} are often used in fitting equation (43).

Keenan (1985) proposes a nonlinearity test for time series that uses \hat{x}_t^2 only and modifies the second step of the RESET test to avoid multicollinearity between \hat{x}_t^2 and \mathbf{X}_{t-1} . Specifically the linear regression (43) is divided into two steps. In step 2(a), one removes linear dependence of \hat{x}_t^2 on \mathbf{X}_{t-1} by fitting the regression

$$\hat{x}_t^2 = \mathbf{X}'_{t-1} \boldsymbol{\beta} + u_t$$

and obtaining the residual $\hat{u}_t = \hat{x}_t^2 - \mathbf{X}_{t-1} \hat{\boldsymbol{\beta}}$. In step 2(b), consider the linear regression

$$\hat{a}_t = \hat{u}_t \boldsymbol{\alpha} + v_t$$

and obtain the sum of squared residuals $SSR_1 = \sum_{t=p+1}^T (\hat{a}_t - \hat{u}_t \hat{\alpha})^2 = \sum_{t=p+1}^T \hat{v}_t^2$ to test the null hypothesis $\alpha = 0$.

The F Test

To improve the power of Keenan’s test and the RESET test, Tsay (1986) uses a different choice of the regressor M_{t-1} . Specifically, he suggests using $M_{t-1} = vech(X_{t-1} X'_{t-1})$, where $vech(A)$ denotes the half-stacking vector of the matrix A using elements on and below the diagonal only. For example, if $p = 2$, then $M_{t-1} = (x_{t-1}^2, x_{t-1}x_{t-2}, x_{t-2}^2)'$. The dimension of M_{t-1} is $p(p + 1)/2$ for an $AR(p)$ model. In practice, the test is simply the usual partial F statistic for testing $\alpha = 0$ in the linear least squares regression

$$x_t = X'_{t-1} \phi + M'_{t-1} \alpha + e_t$$

where e_t denotes the error term. Under the assumption that x_t is a linear $AR(p)$ process, the partial F statistic follows an F distribution with degrees of freedom g and $T - p - g - 1$, where $g = p(p + 1)/2$. We refer to this F test as the Ori- F test. Luukkonen, Saikkonen, and Teräsvirta (1988) further extend the test by augmenting M_{t-1} with cubic terms x_{t-i}^3 for $i = 1, \dots, p$.

Threshold Test

When the alternative model under study is a SETAR model, one can derive specific test statistics to increase the power of the test. One of the specific tests is the likelihood ratio statistic. This test, however, encounters the difficulty of undefined parameters under the null hypothesis of linearity because the threshold is undefined for a linear AR process. Another specific test seeks to transform testing threshold nonlinearity into detecting model changes. It is then interesting to discuss the differences between these two specific tests for threshold nonlinearity.

To simplify the discussion, let us consider the simple case that the alternative model is a 2-regime SETAR model with threshold variable x_{t-d} . The null hypothesis H_0 : x_t follows the lin-

ear $AR(p)$ model

$$x_t = \phi_0 + \sum_{i=1}^p \phi_i x_{t-i} + a_t \tag{45}$$

whereas the alternative hypothesis H_a : x_t follows the SETAR model

$$x_t = \begin{cases} \phi_0^{(1)} + \sum_{i=1}^p \phi_i^{(1)} x_{t-i} + a_{1t} & \text{if } x_{t-d} < r_1 \\ \phi_0^{(2)} + \sum_{i=1}^p \phi_i^{(2)} x_{t-i} + a_{2t} & \text{if } x_{t-d} \geq r_1 \end{cases} \tag{46}$$

where r_1 is the threshold. For a given realization $\{x_t\}_{t=1}^T$ and assuming normality let $l_0(\hat{\phi}, \hat{\sigma}_a^2)$ be the log likelihood function evaluated at the maximum likelihood estimates of $\phi = (\phi_0, \dots, \phi_p)'$ and σ_a^2 . This is easy to compute. The likelihood function under the alternative is also easy to compute if the threshold r_1 is given. Let $l_1(r_1; \hat{\phi}_1, \hat{\sigma}_1^2; \hat{\phi}_2, \hat{\sigma}_2^2)$ be the log likelihood function evaluated at the maximum likelihood estimates of $\phi_i = (\phi_0^{(i)}, \dots, \phi_p^{(i)})'$ and σ_i^2 conditioned on knowing the threshold r_1 . The log likelihood ratio $l(r_1)$ defined as

$$l(r_1) = l_1(r_1; \hat{\phi}_1, \hat{\sigma}_1^2; \hat{\phi}_2, \hat{\sigma}_2^2) - l_0(\hat{\phi}, \hat{\sigma}_a^2)$$

is then a function of the threshold r_1 , which is unknown. Yet under the null hypothesis, there is no threshold and r_1 is not defined. The parameter r_1 is referred to as a nuisance parameter under the null hypothesis. Consequently, the asymptotic distribution of the likelihood ratio is very different from that of the conventional likelihood ratio statistics. (See Chan, 1991, for further details and critical values of the test.) A common approach is to use $l_{\max} = \sup_{v < r_1 < u} l(r_1)$ as the test statistic, where v and u are pre-specified lower and upper bounds of the threshold. Davis (1987) and Andrews and Ploberger (1994) provide further discussion on hypothesis testing involving nuisance parameters under the null hypothesis. Simulation is often used to obtain empirical critical values of the test statistic l_{\max} , which depends on the choices of v and u . The average of $l(r_1)$ over $r_1 \in [v, u]$ is also considered by Andrews and Ploberger as a test statistic.

Tsay (1989) makes use of arranged autoregression and recursive estimation to derive an alternative test for threshold nonlinearity. The arranged autoregression seeks to transfer the SETAR model under the alternative hypothesis H_a into a model change problem with the threshold r_1 serving as the change point. To see this, the SETAR model in equation (46) says that x_t follows essentially two linear models depending on whether $x_{t-d} < r_1$ or $x_{t-d} \geq r_1$. For a realization $\{x_t\}_{t=1}^T$, x_{t-d} can assume values $\{x_1, \dots, X_{T-d}\}$. Let $x_{(1)} \leq x_{(2)} \leq \dots \leq x_{(T-d)}$ be the ordered statistics of $\{x_t\}_{t=1}^{T-d}$ (i.e., arranging the observations in increasing order). The SETAR model can then be written as

$$x_{(j)+d} = \beta_0 + \sum_{i=1}^p \beta_i x_{(j)+d-i} + a_{(j)+d}, \quad (47)$$

$$j = 1, \dots, T-d$$

where $\beta_i = \phi_i^{(1)}$ if $x_{(j)} < r_1$ and $\beta_i = \phi_i^{(2)}$ if $x_{(j)} \geq r_1$. Consequently, the threshold r_1 is a change point for the linear regression in equation (47), and we refer to equation (47) as an arranged autoregression (in increasing order of the threshold x_{t-d}). Note that the arranged autoregression in (47) does not alter the dynamic dependence of x_t on x_{t-i} for $i = 1, \dots, p$ because $x_{(j)+d}$ still depends on $x_{(j)+d-i}$ for $i = 1, \dots, p$. What is done is simply to present the SETAR model in the threshold space instead of in the time space. That is, the equation with a smaller x_{t-d} appears before that with a larger x_{t-d} . The *threshold test* of Tsay (1989) is obtained as follows.

- *Step 1.* Fit equation (47) using $j = 1, \dots, m$, where m is a prespecified positive integer (e.g., 30). Denote the least squares estimates of β_i by $\hat{\beta}_{i,m}$, where m denotes the number of data points used in estimation.
- *Step 2.* Compute the predictive residual

$$\hat{a}_{(m+1)+d} = x_{(m+1)+d} - \hat{\beta}_{0,m} - \sum_{i=1}^p \hat{\beta}_{i,m} x_{(m+1)+d-i}$$

and its standard error. Let $\hat{e}_{(m+1)+d}$ be the standardized predictive residual.

- *Step 3.* Use the recursive least squares method to update the least squares estimates to $\hat{\beta}_{i,m+1}$ by incorporating the new data point $x_{(m+1)+d}$.
- *Step 4.* Repeat steps 2 and 3 until all data points are processed.
- *Step 5.* Consider the linear regression of the standardized predictive residual

$$\hat{e}_{(m+j)+d} = \alpha_0 + \sum_{i=1}^p \alpha_i x_{(m+j)+d-i} + v_t, \quad (48)$$

$$j = 1, \dots, T-d-m$$

and compute the usual F statistic for testing $\alpha_i = 0$ in equation (48) for $i = 0, \dots, p$. Under the null hypothesis that x_t follows a linear AR(p) model, the F ratio has a limiting F distribution with degrees of freedom $p+1$ and $T-d-m-p$.

We refer to the earlier F test as a TAR- F test. The idea behind the test is that under the null hypothesis there is no model change in the arranged autoregression in equation (47) so that the standardized predictive residuals should be close to IID with mean zero and variance 1. In this case, they should have no correlations with the regressors $x_{(m+j)+d-i}$. For further details including formulas for a recursive least squares method and some simulation study on performance of the TAR- F test, see Tsay (1989). The TAR- F test avoids the problem of nuisance parameters encountered by the likelihood ratio test. It does not require knowing the threshold r_1 . It simply tests that the predictive residuals have no correlations with regressors if the null hypothesis holds. Therefore, the test does not depend on knowing the number of regimes in the alternative model. Yet the TAR- F test is not as powerful as the likelihood ratio test if the true model is indeed a 2-regime SETAR model with a known innovational distribution.

Applications

In this subsection, we apply some of the nonlinearity tests discussed previously to five time series. For a real financial time series, an AR model is used to remove any serial correlation

Table 2 Nonlinearity Tests for Simulated Series and Some Log Stock Returns

Note: The sample size of simulated series is 500 and that of stock returns is 864. The BDS test uses $k = 2, \dots, 5$.

in the data, and the tests apply to the residual series of the model. The five series employed are as follows:

1. r_{1t} : A simulated series of IID $N(0,1)$ with 500 observations.
2. r_{2t} : A simulated series of IID Student- t distribution with 6 degrees of freedom. The sample size is 500.
3. a_{3t} : The residual series of monthly log returns of CRSP equal-weighted index from 1926 to 1997 with 864 observations. The linear AR model used is

$$(1 - 0.180B + 0.099B^3 - 0.105B^9)r_{3t} = 0.0086 + a_{3t}$$

4. a_{4t} : The residual series of monthly log returns of CRSP value-weighted index from 1926 to 1997 with 864 observations. The linear AR model used is

$$(1 - 0.098B + 0.111B^3 - 0.088B^5)r_{4t} = 0.0078 + a_{4t}$$

5. a_{5t} : The residual series of monthly log returns of IBM stock from 1926 to 1997 with 864 observations. The linear AR model used is

$$(1 - 0.077B)r_{5t} = 0.011 + a_{5t}$$

Table 2 shows the results of the nonlinearity test. For the simulated series and IBM returns, the F tests are based on an AR(6) model. For the index returns, the AR order is the same as the model given earlier. For the BDS test, we chose $\delta = \hat{\sigma}_a$ and $\delta = 1.5\hat{\sigma}_a$ with $k = 2, \dots, 5$. Also given in the table are the Ljung-Box statistics that confirm no serial correlation in the residual series before applying nonlinearity tests. Compared with their asymptotic critical values, the BDS test and F tests are insignificant at the 5% level for the simulated series. However, the BDS tests are highly significant for the real financial time series. The F tests also show significant results for the index returns, but they fail to suggest nonlinearity in the IBM log returns. In summary, the tests confirm that the simulated series are linear and suggest that the stock returns are nonlinear.

1 MODELING

Nonlinear time series modeling necessarily involves subjective judgment. However, there are some general guidelines to follow. It starts with building an adequate linear model on which nonlinearity tests are based. For financial time series, the Ljung-Box statistics and Engle's test

are commonly used to detect conditional heteroscedasticity. For general series, other tests discussed in the previous section apply. If nonlinearity is statistically significant, then one chooses a class of nonlinear models to entertain. The selection here may depend on the experience of the analyst and the substantive matter of the problem under study.

For volatility models, the order of an ARCH process can often be determined by checking the partial autocorrelation function of the squared series. For GARCH and exponential GARCH models, only lower orders such as (1,1), (1,2), and (2,1) are considered in most applications. Higher order models are hard to estimate and understand. For TAR models, one may use the procedures given in Tong (1990) and Tsay (1989, 1998) to build an adequate model. When the sample size is sufficiently large, one may apply nonparametric techniques to explore the nonlinear feature of the data and choose a proper nonlinear model accordingly; see Chen and Tsay (1993a) and Cai, Fan, and Yao (2000). The MARS procedure of Lewis and Stevens (1991) can also be used to explore the dynamic structure of the data.

Finally, information criteria such as the Akaike information criterion (Akaike, 1974) and the generalized odd ratios in Chen, McCulloch, and Tsay (1997) can be used to discriminate between competing nonlinear models. The chosen model should be carefully checked before it is used for prediction.

FORECASTING

Unlike the linear model, there exist no closed-form formulas to compute forecasts of most nonlinear models when the forecast horizon is greater than 1. We use parametric bootstraps to compute nonlinear forecasts. It is understood that the model used in forecasting has been rigorously checked and is judged to be adequate for the series under study. By a model, we mean the dynamic structure and innovational distri-

butions. In some cases, we may treat the estimated parameters as given.

Parametric Bootstrap

Let T be the forecast origin and ℓ be the forecast horizon ($\ell > 0$). That is, we are at time index T and interested in forecasting $x_{T+\ell}$. The parametric bootstrap considered computes realizations $x_{T+1}, \dots, x_{T+\ell}$ sequentially by (a) drawing a new innovation from the specified innovational distribution of the model, and (b) computing x_{T+1} using the model, data, and previous forecasts $x_{T+1}, \dots, x_{T+i-1}$. This results in a realization for $x_{T+\ell}$. The procedure is repeated M times to obtain M realizations of $x_{T+\ell}$ denoted by $\{x_{T+\ell}^{(j)}\}_{j=1}^M$. The point forecast of $X_{T+\ell}$ is then the sample average of $x_{T+\ell}^{(j)}$. Let the forecast be $x_T(\ell)$. We used $M = 3000$ in some applications and the results seem fine. The realizations $\{x_{T+\ell}^{(j)}\}_{j=1}^M$ can also be used to obtain an empirical distribution of $x_{T+\ell}$. We make use of this empirical distribution later to evaluate forecasting performance.

Forecasting Evaluation

There are many ways to evaluate the forecasting performance of a model, ranging from directional measures to magnitude measures to distributional measures. A directional measure considers the future direction (up or down) implied by the model. Predicting that tomorrow's S&P 500 index will go up or down is an example of directional forecasts that are of practical interest. Predicting the year-end value of the daily S&P 500 index belongs to the case of magnitude measure. Finally, assessing the likelihood that the daily S&P 500 index will go up 10% or more between now and the year end requires knowing the future conditional probability distribution of the index. Evaluating the accuracy of such an assessment needs a distributional measure.

In practice, the available data set is divided into two subsamples. The first subsample of the data is used to build a nonlinear model, and the second subsample is used to evaluate the

forecasting performance of the model. We refer to the two subsamples of data as estimation and forecasting subsamples. In some studies, a rolling forecasting procedure is used in which a new data point is moved from the forecasting subsample into the estimation subsample as the forecast origin advances. In what follows, we briefly discuss some measures of forecasting performance that are commonly used in the literature. Keep in mind, however, that there exists no widely accepted single measure to compare models. A utility function based on the objective of the forecast might be needed to better understand the comparison.

Directional Measure

A typical measure here is to use a 2 × 2 contingency table that summarizes the number of “hits” and “misses” of the model in predicting ups and downs of $x_{T+\ell}$ in the forecasting subsample. Specifically, the contingency table is given as

Actual	Predicted		
	up	down	
up	m_{11}	m_{12}	m_{10}
down	m_{21}	m_{22}	m_{20}
	m_{01}	m_{02}	m

where m is the total number of ℓ -step ahead forecasts in the forecasting subsample, m_{11} is the number of “hits” in predicting upward movements, m_{21} is the number of “misses” in predicting downward movements of the market, and so on. Larger values in m_{11} and m_{22} indicate better forecasts. The test statistic

$$X^2 = \sum_{i=1}^2 \sum_{j=1}^2 \frac{(m_{ij} - m_{i0}m_{0j}/m)^2}{m_{i0}m_{0j}/m}$$

can then be used to evaluate the performance of the model. A large χ^2 signifies that the model outperforms the chance of random choice. Under some mild conditions, χ^2 has an asymptotic chi-squared distribution with 1 degree of free-

dom. For further discussion of this measure, see Dahl and Hylleberg (1999).

For illustration of the directional measure, consider the 1-step ahead probability forecasts of the 8-4-1 feed-forward neural network shown in Figure 9. The 2 × 2 table of “hits” and “misses” of the network is

Actual	Predicted		
	up	down	
up	12	2	14
down	8	2	10
	20	4	24

The table shows that the network predicts the upward movement well, but fares poorly in forecasting the downward movement of the stock. The chi-squared statistic of the table is 0.137 with 77-value 0.71. Consequently, the network does not significantly outperform a random-walk model with equal probabilities for “upward” and “downward” movements.

Magnitude Measure

Three statistics are commonly used to measure performance of point forecasts. They are the mean squared error (MSE), mean absolute deviation (MAD), and mean absolute percentage error (MAPE). For ℓ -step ahead forecasts, these measures are defined as

$$MSE(\ell) = \frac{1}{m} \sum_{j=0}^{m-1} [x_{T+\ell+j} - x_{T+j}(\ell)]^2 \tag{49}$$

$$MAD(\ell) = \frac{1}{m} \sum_{j=0}^{m-1} |x_{T+\ell+j} - x_{T+j}(\ell)| \tag{50}$$

$$MAPE(\ell) = \frac{1}{m} \sum_{j=0}^{m-1} \left| \frac{x_{T+j}(\ell)}{x_{T+j+\ell}} - 1 \right| \tag{51}$$

where m is the number of ℓ -step ahead forecasts available in the forecasting subsample.

In application, one often chooses one of the above three measures, and the model with the smallest magnitude on that measure is regarded as the best ℓ -step ahead forecasting

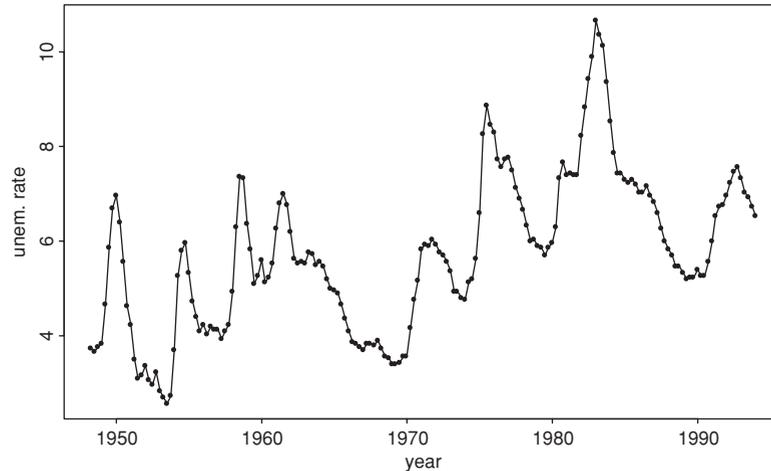

Figure 11 Time Plot of the U.S. Quarterly Unemployment Rate, Seasonally Adjusted, from 1948 to 1993

model. It is possible that different ℓ may result in selecting different models. The measures also have other limitations in model comparison; see, for instance, Clements and Hendry (1993).

Distributional Measure

Practitioners recently began to assess forecasting performance of a model using its predictive distributions. Strictly speaking, a predictive distribution incorporates parameter uncertainty in forecasts. We call it conditional predictive distribution if the parameters are treated as fixed. The empirical distribution of $x_{T+\ell}$ obtained by the parametric bootstrap is a conditional predictive distribution. This empirical distribution is often used to compute a distributional measure. Let $u_T(\ell)$ be the percentile of the observed $x_{T+\ell}$ in the prior empirical distribution. We then have a set of m percentiles $\{u_{T+j}(\ell)\}_{j=0}^{m-1}$, where again m is the number of ℓ -step ahead forecasts in the forecasting subsample. If the model entertained is adequate, $\{u_{T+j}(\ell)\}$ should be a random sample from the uniform distribution on $[0, 1]$. For a sufficiently large m , one can compute the Kolmogorov-Smirnov statistic of $\{u_{T+j}(\ell)\}$ with respect to uniform $[0, 1]$. The statistic can be used for both model checking and forecasting comparison.

2 APPLICATION

In this section, we illustrate nonlinear time series models by analyzing the quarterly U.S. civilian unemployment rate, seasonally adjusted, from 1948 to 1993. This series was analyzed in detail by Montgomery, Zarnowitz, Tsay, and Tiao (1998). We repeat some of the analyses here using nonlinear models. Figure 11 shows the time plot of the data. Well-known characteristics of the series include that (a) it tends to move countercyclically with U.S. business cycles, and (b) the rate rises quickly but decays slowly. The latter characteristic suggests that the dynamic structure of the series is nonlinear.

Denote the series by x_t and let $\Delta x_t = x_t - x_{t-1}$ be the change in unemployment rate. The linear model

$$(1 - 0.31B^4)(1 - 0.65B)\Delta x_t = (1 - 0.78B^4)a_t, \\ \hat{\sigma}_a^2 = 0.090 \quad (52)$$

was built by Montgomery et al. (1998), where the standard errors of the three coefficients are 0.11, 0.06, and 0.07, respectively. This is a seasonal model even though the data were seasonally adjusted. It indicates that the seasonal adjustment procedure used did not successfully remove the seasonality. This model is used as a benchmark model for forecasting comparison.

Table 3 Nonlinearity Test for Changes in the U.S. Quarterly Unemployment Rate: 1948.II–1993.IV

Type	Ori-F	LST	TAR(1)	TAR(2)	TAR(3)	TAR(4)
Test	2.80	2.83	2.41	2.16	2.84	2.98
<i>p</i> value	.0007	.0002	.0298	.0500	.0121	.0088

Note: An AR(5) model was used in the tests, where LST denotes the test of Luukkonen et al. (1988) and TAR(*d*) means threshold test with delay *d*.

To test for nonlinearity, we apply some of the nonlinearity tests discussed earlier in this entry with an AR(5) model for the differenced series Δx_t . The results are given in Table 3. All of the tests reject the linearity assumption. In fact, the linearity assumption is rejected for all AR(*p*) models we applied, where $p = 2, \dots, 10$.

Using a modeling procedure similar to that of Tsay (1989), Montgomery et al. (1998) build the following TAR model for the Δx_t series:

$$\Delta x_t = \begin{cases} 0.01 + 0.73\Delta x_{t-1} + 0.10\Delta x_{t-2} + a_{1t} & \text{if } \Delta x_{t-2} \leq 0.1, \\ 0.18 + 0.80\Delta x_{t-1} - 0.56\Delta x_{t-2} + a_{2t} & \text{otherwise} \end{cases} \quad (53)$$

The sample variances of a_{1t} and a_{2t} are 0.76 and 0.165, respectively, the standard errors of the three coefficients of regime 1 are 0.03, 0.10, and 0.12, respectively, and those of regime 2 are 0.09, 0.1, and 0.16. This model says that the change in the U.S. quarterly unemployment rate, Δx_t , behaves like a piecewise linear model in the reference space of $x_{t-2} - x_{t-3}$ with threshold 0.1. Intuitively, the model implies that the dynamics of unemployment act differently depending on the recent change in the unemployment rate. In the first regime, the unemployment rate has had either a decrease or a minor increase. Here the economy should be stable, and essentially the change in the rate follows a simple AR(1) model because the lag-2 coefficient is insignificant. In the second regime, there is a substantial jump in the unemployment rate (0.1 or larger). This typically corresponds to the contraction phase in the business cycle. It is also the period during which government interventions and industrial restructuring are likely to occur. Here Δx_t fol-

lows an AR(2) model with a positive constant, indicating an upward trend in x_t . The AR(2) polynomial contains two complex characteristic roots, which indicate possible cyclical behavior in Δx_t . Consequently, the chance of having a turning point in x_t increases, suggesting that the period of large increases in x_t should be short. This implies that the contraction phases in the U.S. economy tend to be shorter than the expansion phases.

Applying a Markov chain Monte Carlo method, Montgomery et al. (1998) obtain the following Markov switching model for Δx_t :

$$\Delta x_t = \begin{cases} -0.07 + 0.38\Delta x_{t-1} - 0.05\Delta x_{t-2} + \epsilon_{1t} & \text{if } s_t = 1 \\ 0.16 + 0.86\Delta x_{t-1} - 0.38\Delta x_{t-2} + \epsilon_{2t} & \text{if } s_t = 2 \end{cases} \quad (54)$$

The conditional means of Δx_t are -0.10 for $s_t = 1$ and 0.31 for $s_t = 2$. Thus, the first state represents the expansionary periods in the economy, and the second state represents the contractions. The sample variances of ϵ_{1t} and ϵ_{2t} are 0.031 and 0.192, respectively. The standard errors of the three parameters in state $s_t = 1$ are 0.03, 0.14, and 0.11, and those of state $s_t = 2$ are 0.04, 0.13, and 0.14, respectively. The state transition probabilities are $P(s_t = 2 | s_{t-1} = 1) = 0.084(0.060)$ and $P(s_t = 1 | s_{t-1} = 2) = 0.126(0.053)$, where the number in parentheses is the corresponding standard error. This model implies that in the second state the unemployment rate x_t has an upward trend with an AR(2) polynomial possessing complex characteristic roots. This feature of the model is similar to the second regime of the TAR model in equation (53). In the first state, the unemployment

rate x_t has a slightly decreasing trend with a much weaker autoregressive structure.

Forecasting Performance

A rolling procedure was used by Montgomery et al. (1998) to forecast the unemployment rate x_t . The procedure works as follows:

1. Begin with forecast origin $T = 83$, corresponding to 1968.II, which was used in the literature to monitor the performance of various econometric models in forecasting unemployment rate. Estimate the linear, TAR, and MSA models using the data from 1948.I to the forecast origin (inclusive).
2. Perform 1-quarter to 5-quarter ahead forecasts and compute the forecast errors of each model. Forecasts of nonlinear models used are computed by using the parametric bootstrap method explained earlier in this entry.
3. Advance the forecast origin by 1 and repeat the estimation and forecasting processes until all data are employed.
4. Use MSE and mean forecast error to compare performance of the models.

Table 4 shows the relative MSE of forecasts and mean forecast errors for the linear model in equation (52), the TAR model in equation (53), and the MSA model in equation (54), using the linear model as a benchmark. The comparisons are based on overall performance as well as the status of the U.S. economy at the forecast origin. From the table, we make the following observations:

1. For the overall comparison, the TAR model and the linear model are very close in MSE, but the TAR model has smaller biases. Yet the MSA model has the highest MSE and smallest biases.
2. For forecast origins in economic contractions, the TAR model shows improvements over the linear model both in MSE and bias. The MSA model also shows some improvement over the linear model, but the improvement is not as large as that of the TAR model.

Table 4 Out-of-Sample Forecast Comparison Among Linear, TAR, and MSA Models for the U.S. Quarterly Unemployment Rate

(A) Relative MSE of Forecast					
Model	1-step	2-step	3-step	4-step	5-step
(a) Overall Comparison					
Linear	1.00	1.00	1.00	1.00	1.00
TAR	1.00	1.04	0.99	0.98	1.03
MSA	1.19	1.39	1.40	1.45	1.61
MSE	0.08	0.31	0.67	1.13	1.54
(b) Forecast Origins in Economic Contractions					
Linear	1.00	1.00	1.00	1.00	1.00
TAR	0.85	0.91	0.83	0.72	0.72
MSA	0.97	1.03	0.96	0.86	1.02
MSE	0.22	0.97	2.14	3.38	3.46
(c) Forecast Origins in Economic Expansions					
Linear	1.00	1.00	1.00	1.00	1.00
TAR	1.06	1.13	1.10	1.15	1.17
MSA	1.31	1.64	1.73	1.84	1.87
MSE	0.06	0.21	0.45	0.78	1.24
(B) Mean of Forecast Errors					
Model	1-step	2-step	3-step	4-step	5-step
(a) Overall Comparison					
Linear	0.03	0.09	0.17	0.25	0.33
TAR	-0.10	-0.02	-0.03	-0.03	-0.01
MSA	0.00	-0.02	-0.04	-0.07	-0.12
(b) Forecast Origins in Economic Contractions					
Linear	0.31	0.68	1.08	1.41	1.38
TAR	0.24	0.56	0.87	1.01	0.86
MSA	0.20	0.41	0.57	0.52	0.14
(c) Forecast Origins in Economic Expansions					
Linear	-0.01	0.00	0.03	0.08	0.17
TAR	-0.05	-0.11	-0.17	-0.19	-0.14
MSA	-0.03	-0.08	-0.13	-0.17	-0.16

Note: The starting forecast origin is 1968.II, where the row marked by "MSE" shows the MSE of the benchmark linear model.

3. For forecast origins in economic expansions, the linear model outperforms both nonlinear models.

The results suggest that the contributions of nonlinear models over linear ones in forecasting the U.S. quarterly unemployment rate are

mainly in the periods when the U.S. economy is in contraction. This is not surprising because, as mentioned before, it is during the economic contractions that government interventions and industrial restructuring are most likely to occur. These external events could introduce nonlinearity in the U.S. unemployment rate. Intuitively, such improvements are important because it is during the contractions that people pay more attention to economic forecasts.

KEY POINTS

- Nonlinearity exists in many financial data, including log returns of widely used market indexes such as CRSP equal- and value-weight indexes.
- Nonlinearity also appears in asset volatility. Indeed, simple threshold models such as the threshold GARCH model can be used to better describe the behavior of asset volatility. The model has been used to model the leverage effect between return and volatility.
- Simple nonparametric methods such as the local linear regression method can be used to provide a deeper understanding of interest rate dynamics.
- The unemployment rate example shows that, even though nonlinear models may not outperform linear ones in all forecast origins, they can provide more accurate forecasts when the U.S. economy is under contraction. This is useful because people in general pay more attention to forecasts during economic recession.
- Among the nonlinear models, the Markov switching model has the smallest bias in out-of-sample prediction. The model, however, has a larger mean square of forecast errors than the threshold autoregressive model. This behavior is consistent with the structure of the model because the true states of the economy are never certain under the switching model.

Robust Estimates of Betas and Correlations

THOMAS K. PHILIPS, PhD

Regional Head of Investment Risk and Performance, BNP Paribas Investment Partners

Abstract: The Theil-Sen estimator is an exceptionally simple and robust linear regression estimator, affording estimates of slope and intercept that are virtually identical to their ordinary least squares counterparts in the absence of outliers, but which do not change appreciably in the presence of outliers. In fact, with univariate data, it improves on ordinary least squares in almost every way imaginable, and it is therefore a striking fact that this remarkable estimator is not universally known and used. It can be used to derive robust estimates of beta and the correlation coefficient that are virtually identical to their classical counterparts when asset returns are normally distributed, and which are significantly more robust when asset returns are highly skewed or contaminated with outliers.

Point estimates of betas and correlations are most often obtained using *ordinary least squares (OLS)* and the standard maximum likelihood estimator, respectively. While these estimators are clearly optimal when asset returns are normally distributed, and when we hold no view on their prior distribution, they can be far from optimal when these conditions are not satisfied. In this entry, a novel explanation of OLS is provided and is then used to motivate a *robust* univariate *regression* algorithm due to Theil (1950) and Sen (1968). This estimator is then used to obtain remarkably robust (i.e., outlier resistant) estimates of asset *betas*, asset *correlations*, and *non-negative definite* correlation and *covariance* matrices.

OLS REVISITED

Generations of students have learned OLS in the way depicted pictorially in Figure 1. We are given a set of points, each with an abscissa (or x value) and an ordinate (or y value), and which are displayed on a scatter plot in the $X - Y$ plane. All errors are assumed to be concentrated in the ordinates. The abscissae are assumed to be known with certainty. The i^{th} point has coordinates (x_i, y_i) , and the collection of points visually evidences a noisy, but linear, relationship between the x 's and the y 's. The object of OLS is to find a straight line, the line of best fit, with slope β_{OLS} and intercept α_{OLS} , and which minimizes the sum of squared vertical distances (or errors) from the points to this line.

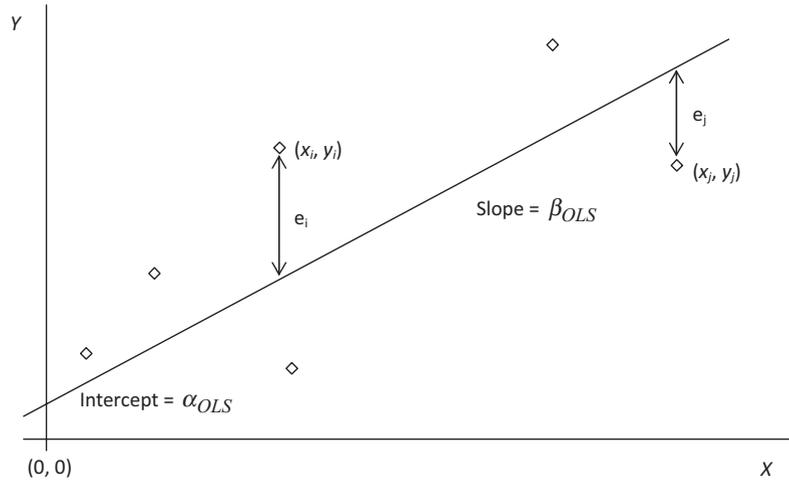

Figure 1 Ordinary Least Squares—Classical Depiction

This pictorial representation has become so firmly embedded in our consciousness that we take its geometry and its formulation for granted. But consider that the method dates back to 1800, and the fact that it was independently discovered by Carl Friedrich Gauss and Joseph-Louis Lagrange, who surely rank among the greatest mathematicians of all time, and it should come as no surprise that this textbook depiction of OLS hides more than one secret. In this section, we expose two of its secrets.

We start our exploration of OLS with Figure 2, which plots the same set of points as Figure 1, but now, instead of drawing a single line of best fit through the entire data set, we choose two specific points, (x_i, y_i) and (x_j, y_j) , draw the unique straight line joining them and project it back till it intersects the Y axis. This line has slope β_{ij} and intercept α_{ij} , where β_{ij} and α_{ij} are given by:

$$\beta_{ij} = \frac{y_i - y_j}{x_i - x_j}, \tag{1}$$

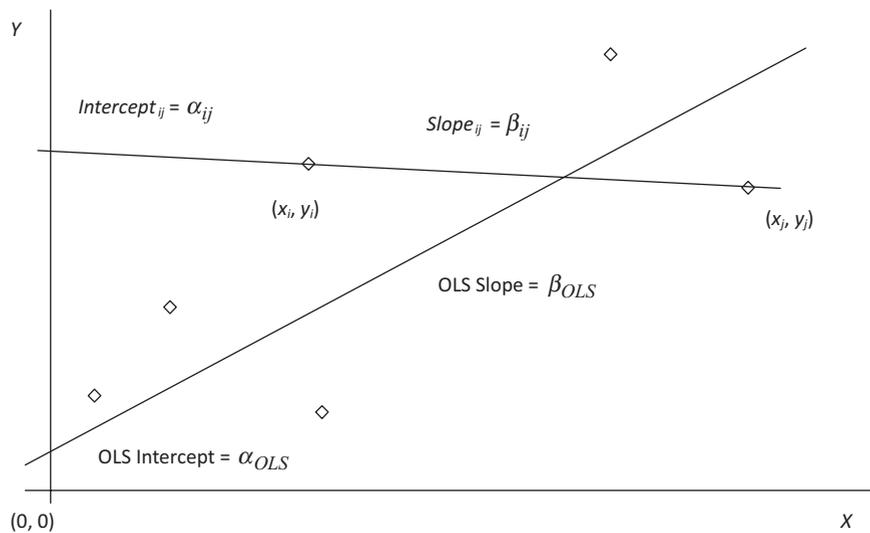

Figure 2 Ordinary Least Squares—Alternative Depiction

and

$$\alpha_{ij} = \frac{x_i \times y_j - x_j \times y_i}{x_i - x_j} \quad (2)$$

On comparing Figures 1 and 2, it is clear that β_{OLS} must necessarily lie between $\min_{i,j} \beta_{ij}$ and $\max_{i,j} \beta_{ij}$, both endpoints inclusive, and that α_{OLS} must likewise lie between $\min_{i,j} \alpha_{ij}$ and $\max_{i,j} \alpha_{ij}$. The OLS slope and intercept can therefore be written as weighted averages of all $\binom{N}{2} = \frac{N(N-1)}{2}$ pairwise slopes and intercepts for some nonnegative sets of weights, that is,

$$\beta_{OLS} = \sum_i \sum_j w_{ij} \beta_{ij}, \quad \sum_i \sum_j w_{ij} = 1, \quad w_{ij} \geq 0 \quad (3)$$

and

$$\alpha_{OLS} = \sum_i \sum_j v_{ij} \alpha_{ij}, \quad \sum_i \sum_j v_{ij} = 1, v_{ij} \geq 0 \quad (4)$$

In any particular situation, these weights are not unique, as equations (3) and (4) are enormously overdetermined, and we therefore seek a set of strictly positive weights that simultaneously solves both equations for an arbitrary collection of points. Such a set of weights can be identified using some clever guesswork motivated by the following observation: If (x_i, y_i) and (x_j, y_j) are close together, then any error in either ordinate will induce significant errors in β_{ij} and α_{ij} . Pairs of points that are far apart are much less susceptible to this problem. We ought, therefore, to overweight slopes and intercepts derived from pairs of points that are far apart relative to those that are derived from pairs of points that are close together.

Next, as all the error is concentrated in the abscissae, and as the ordinates are known with certainty, the weights must be a function only of $(x_i - x_j)$ —they cannot depend on $(y_i - y_j)$. Finally, the function must be even, because some weights would be negative if it were odd. Some tedious and not particularly enlightening alge-

bra shows our intuition to be correct, that is,

$$w_{ij} = v_{ij} = \frac{(x_i - x_j)^2}{\sum_k \sum_l (x_k - x_l)^2} \quad (5)$$

It follows that

$$\beta_{OLS} = \frac{\sum_i \sum_j \beta_{ij} (x_i - x_j)^2}{\sum_k \sum_l (x_k - x_l)^2} \quad (6)$$

and

$$\alpha_{OLS} = \frac{\sum_i \sum_j \alpha_{ij} (x_i - x_j)^2}{\sum_k \sum_l (x_k - x_l)^2} \quad (7)$$

Equations (6) and (7) yield OLS' first little secret—the line of best fit is just an appropriately weighted average of all possible lines that could be drawn using this data set! While this argument does not readily extend to the multivariate case, it does give us a fresh perspective on OLS, which now stands exposed as a clever and computationally efficient weighting scheme over the set of unique straight lines drawn through all possible pairs of points. A proof of this result, which is usually credited to Sen (1968), can be found in Heitman and Ord (1985).

Its second little secret lies in its focus on squared errors. Why should it be the second, and not the fourth or the sixty-fourth power of the error that is minimized? To answer this question, recall the way in which the OLS slope and intercept are defined:

$$\begin{aligned} \alpha_{OLS}, \beta_{OLS} &= \arg \min \sum_i error_i^2 \\ &= \arg \min \sum_i (y_i - \alpha_{OLS} - \beta_{OLS} \times x_i)^2 \end{aligned} \quad (8)$$

Solving this minimization problem requires us to compute the partial derivatives of the sum of squared errors with respect to α_{OLS} and β_{OLS} , and to equate the resulting expressions to 0. This results in a set of linear equations that can be solved in closed form (the solution was known to both Gauss and Lagrange). If, however, the error is raised to a power other than

two, we would have to solve a set of nonlinear equations, which do not, in general, admit a closed form solution—they must be solved numerically on a computer, a tool that neither Gauss nor Lagrange had access to. That said, raising the error to any even power (or even making it the argument of any even function) and then performing the indicated minimization numerically will result in a line that is optimal under that measure, though its slope and intercept will not, in general, equal the OLS slope and intercept.

All of this leads to our second insight—the mathematical formulation of OLS is driven by thoroughly practical considerations. In 1800, anything else simply couldn't be (and for that matter, still can't be) solved analytically! Having exposed these two little secrets of OLS, we now describe a better way in which to compute univariate regressions and explore its application to the estimation of beta and the correlation coefficient, as well as to the estimation of positive definite correlation and covariance matrices.

THEIL-SEN REGRESSION

The *Theil-Sen regression* algorithm (Thiel, 1950; Sen, 1968) is a robust alternative to univariate OLS that performs particularly well in the presence of outliers (loosely, in the presence of large, sporadic errors that are anything but Gaussian). It has long been known that OLS is acutely sensitive to errors in its inputs, and it is immediately apparent from equations (6) and (7) that even a single outlier can induce arbitrarily large errors in β_{OLS} and α_{OLS} .

Thiel (1950) and Sen (1968) propose a novel solution to this problem—they propose using the median of all $\binom{N}{2} = \frac{N(N-1)}{2}$ slopes to estimate the slope of the regression line, and choose the intercept to force the median error to 0. The primary difference between their methods is that Thiel uses all available observations, while Sen restricts attention to the subset of observations with distinct abscissae, that is, the set of

points for which $x_i \neq x_j$, and replaces each set of points that share the same abscissa with a single point whose ordinate is the average of their ordinates.

Formally, the Theil-Sen estimates of slope and intercept are given by:

$$\beta_{TS} = \text{median}_{i,j} \{ \beta_{ij} \} \quad (9)$$

and

$$\alpha_{TS} = \text{median}_{i,j} \{ y_i - \beta_{TS} \times x_i \} \quad (10)$$

This regression has been widely studied. Peng, Wang, and Wang (2008), for example, show that it is strongly consistent and super-efficient, and derive its asymptotic distribution. Interestingly, the median has long been used as a robust estimator of the mean for symmetric distributions, but this appears to be the first known application of the median to the estimation of regression coefficients.

We illustrate the superiority of Theil-Sen regression over OLS via simulations, the results of which are displayed in Tables 1 and 2. When the distribution of errors is normal, the distributions of β_{TS} and α_{TS} are almost identical to those of β_{OLS} and α_{OLS} . When the errors are drawn from a highly skewed distribution, or when the data are contaminated with significant amounts of noise, the distributions of β_{TS} and α_{TS} are far less variable than those of β_{OLS} and α_{OLS} .

These results are generated as follows. Using a high-quality random number generator (Mersenne twister), we create two independent random vectors, X and Y , both of length 100, and drawn from one of two distributions—unit normal and Pareto(2). We then regress Y against X using both OLS and the Theil-Sen regression. As the vectors are independent, the distribution of the slope and the intercept of the regression lines should be centered at 0 and $E[X]$, respectively.

We run 10,000 simulations to ensure that the 99% confidence intervals on our estimates are extremely tight (the width of the confidence interval is inversely proportional to the square root of the number of simulation runs), and

Table 1 Theil-Sen Regression vs. OLS: Normally Distributed Random Variables

Percentiles	1	5	10	25	50	75	90	95	99

Theil-Sen Mean Square	0.69	0.77	0.81	0.89	0.98	1.08	1.17	1.24	1.35
Least Squares Mean Square Err	0.69	0.76	0.81	0.88	0.98	1.07	1.16	1.23	1.33
Theil-Sen Median	0	0	0	0	0	0	0	0	0
Least Squares Median Error	-0.17	-0.12	-0.09	-0.05	0	0.05	0.09	0.12	0.18

Tables 1 and 2 display various percentiles of the distribution of the slope, the intercept, and the mean squared error (i.e., the sum of squared errors divided by 100) for both OLS and the Theil-Sen regression.

The first simulation, for normal random variables, illustrates how close the Theil-Sen algorithm is to OLS in the special case when OLS is clearly optimal. The second simulation illustrates its robustness with Pareto(2) random variables, whose distribution is highly skewed, and whose long tails serve as proxies for outliers.

When X and Y are normally distributed (Table 1), the median slope, the interquartile range for the slope (the difference between the 75th and the 25th percentiles), and the MSE for the two algorithms are essentially identical. The same holds true even when we look at a 90% range (the difference between the 5th and the 95th percentiles). However, when X and Y are drawn from a Pareto(2) distribution (Table 2), the performance of the two algorithms diverges: The interquartile range for the slope is 40% smaller for the Theil-Sen regression (0.06 vs. 0.10 for OLS) and an astonishing 60% smaller

for the 90% range (0.16 vs. 0.41), though the median MSE rises by about 12%.

The median slope remains 0 for the Theil-Sen regression, but exhibits a slight downward bias for OLS. The range of the intercept for the Theil-Sen regression is slightly larger than it is for OLS, but this is driven entirely by the fact that the Theil-Sen intercept is chosen to force the median error to 0, while the OLS intercept is chosen to minimize the sum of squared errors.

These simulations clearly show that the Theil-Sen regression gives up nothing to OLS when X and Y are normally distributed and is at a significant advantage when they are not. Similar results are obtained when either X or Y is contaminated with outliers. In all such experiments, the advantage of the Theil-Sen approach is readily apparent. In fact, it can be shown that as many as 29% of the data points can be corrupted with errors of arbitrary size before the Theil-Sen estimates of slope and intercept start to break down.

Given these results, and the accompanying fact that the vast majority of regressions run in practice are univariate, it is surprising that the Theil-Sen regression is not more widely used

Table 2 Theil-Sen Regression vs. OLS: Pareto(2) Distributed Random Variables

Percentiles	1	5	10	25	50	75	90	95	99
Theil-Sen Slope	-0.12	-0.07	-0.05	-0.03	0	0.03	0.06	0.09	0.14
Least Squares Slope	-0.35	-0.18	-0.13	-0.07	-0.02	0.03	0.13	0.23	0.65
Theil-Sen Intercept	1.17	1.24	1.28	1.34	1.41	1.49	1.57	1.62	1.74
Least Squares Intercept	0.98	1.49	1.62	1.78	1.95	2.16	2.41	2.62	3.44
Theil-Sen Mean Sqr Err	0.59	0.88	1.11	1.67	2.83	5.46	12.29	22.67	107.54
Least Squares Mean Sqr Err	0.52	0.78	0.98	1.47	2.53	4.97	11.54	21.47	104.8
Theil-Sen Median Error	0	0	0	0	0	0	0	0	0
Least Squares Median Error	-1.51	-0.97	-0.83	-0.64	-0.5	-0.4	-0.32	-0.28	-0.22

and appreciated. This may in part be driven by the fact that Theil-Sen regression, unlike OLS, does not generalize naturally to the case where there are many independent variables, as the median is inherently a one-dimensional measure.

A number of attempts have been made to create multivariate extensions of the Theil-Sen regression, the two most popular ones being the iterative Gauss-Seidel method described by Hastie and Tibshirani (1990) and the elemental subset method of Oja and Niinimaa (1984), which is described in Rousseeuw and Leroy (1987). Unfortunately, neither approach is entirely reliable in practice, and it is easy to find simple examples for which they converge to the wrong solution, particularly when the relationship being modeled is nonlinear.

ROBUST ESTIMATES OF BETA

The beta of an asset Y with respect to the market portfolio X plays a central role in modern finance as a result of the capital asset pricing model (Treynor, 1961; Sharpe, 1964; Lintner,

1965; and Mossin, 1966), and is defined to be

$$\beta_{Y|X} = \frac{\text{Cov}(X, Y)}{\sigma_X^2} \quad (11)$$

This quantity is, of course, just the slope coefficient in a univariate regression, and is precisely what OLS estimates. The application of the Theil-Sen regression algorithm to the estimation of beta is obvious—the Theil-Sen estimate of slope ought to provide us a more robust estimate of the historical of a security than the corresponding OLS estimate.

The advantages of the Theil-Sen estimator of beta are made clear by the following estimate of the beta of IBM around the crash of 1987. Starting on July 1, 1987, and ending on December 31, 1987, we estimate IBM's β by regressing its daily return for the most recent 132 days (or 6 months) against the corresponding daily return of the S&P 500. As can be seen from Figure 3, the Theil-Sen estimate is far more stable than the OLS estimate. In particular, it does not jump sharply after the 20% drop in the S&P 500 on October 19 as does the OLS beta, just as one would expect given its robustness.

While this is clearly an extreme example of a single outlier corrupting an estimate of beta,

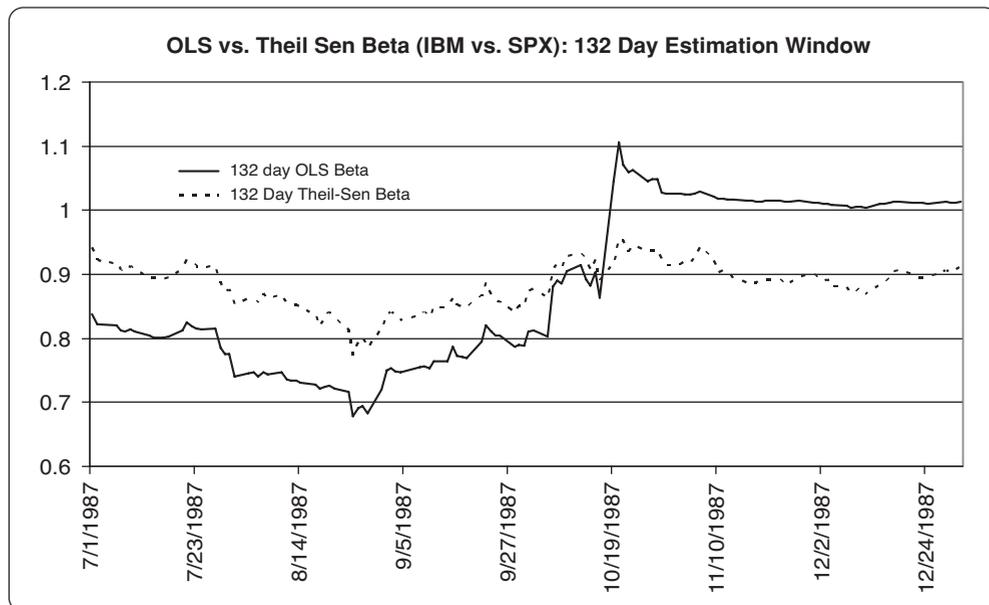

Figure 3 OLS vs. Theil-Sen Estimates of Beta: July 1, 1987, to December 31, 1987

outliers in financial data are far more common than is usually assumed, and they are not easily detected, as they influence many classical estimators in a way that masks their presence. One popular method of identifying and removing outliers is to remove points that lie more than three sample standard deviations away from the regression line.

Unfortunately, outliers can so distort the slope and intercept of the regression line, as well as the sample standard deviation of the errors, that all the points, including the outliers, will be found to lie within three sample standard deviations of the regression line! In general, filtering data using classical estimators to identify outliers works poorly in practice, and it proves far more effective to use estimators that are inherently robust to outliers.

The Theil-Sen estimate of beta can be further adjusted for the effects of nonsynchronous trading using the Scholes-Williams (1977) or Dimson (1979) corrections and can be shrunk cross-sectionally using a Bayesian correction as is done in Vasicek (1973). In each case, the Theil-Sen estimates of beta will provide a more robust point from which to start building an enhanced estimate of beta.

The Dimson correction sums contemporaneous and lagged betas for the asset to create an overall beta that accounts for the fact that an asset may have both a contemporaneous and a lagged response to market shocks, that is,

$$\beta_{Y|X}^{Dimson} = \sum_{i=0}^k \beta_{Y_t|X_{t-i}} \quad (12)$$

When using daily data, k is commonly set to 4 (i.e., one week's data), and when using monthly data, it is most commonly set to 1, so as not to pick up spurious responses from shocks in the distant past.

Vasicek's (1973) correction is a Bayesian correction, which allows the user to reflect information gleaned from the (known) cross-sectional distribution of betas to enhance an unconditional estimate of beta. In particular, Vasicek (1973) assumes that the prior distribution of

betas is normal and shows that the maximum a posteriori estimate of beta is a linear combination of its initial estimate and its cross-sectional mean, that is,

$$\beta_{Y|X}^{Vasicek} = w_Y \times \beta_{Y|X} + (1 - w_Y) \times \beta_{average} \quad (13)$$

where

$$w_Y = \frac{\sigma_{Cross-Sectional}^2}{\sigma_{\beta(Y|X)}^2 + \sigma_{Cross-Sectional}^2} \quad (14)$$

$\sigma_{\beta(Y|X)}^2$ is the variance of $\beta_{Y|X}$, and $\sigma_{Cross-Sectional}^2$ is the cross-sectional variance of the betas of the entire universe of securities under consideration at this point in time. A particularly simple and reasonably effective implementation of this method sets $w_Y = 0.5$ for all assets and at all points in time. Both techniques see use in the enhanced estimation of beta across a wide range of asset classes in Frazzini and Pedersen (2010).

ROBUST ESTIMATES OF CORRELATION

To derive a robust estimate of the correlation coefficient, we rewrite and re-interpret the expression for the correlation coefficient in a novel way, and then show how it can be estimated using two Theil-Sen regressions. Recall the definition of the correlation between two random variables X and Y :

$$\rho_{X,Y} = \frac{Cov(X, Y)}{\sigma_X \times \sigma_Y} \quad (15)$$

where $Cov(X, Y)$ is the covariance between X and Y , and σ_X and σ_Y are the standard deviations of X and Y , respectively. This expression can be rewritten as

$$\begin{aligned} \rho_{X,Y} &= \sqrt{\frac{Cov(X, Y)^2}{\sigma_X^2 \times \sigma_Y^2}} \\ &= \sqrt{\frac{Cov(X, Y)}{\sigma_X^2} \times \frac{Cov(X, Y)}{\sigma_Y^2}} \\ &= \sqrt{\beta_{Y|X} \times \beta_{X|Y}} \end{aligned} \quad (16)$$

Table 3 Distribution of Theil-Sen Estimates of Correlation vs. Standard Maximum Likelihood Estimate: Normally Distributed Random Variables

Percentiles	1	5	10	25	50	75	90	95	99
Theil-Sen correlation	-0.24	-0.17	-0.14	-0.07	0	0.07	0.13	0.18	0.25
Maximum Likelihood correlation	-0.23	-0.17	-0.13	-0.07	0	0.07	0.13	0.16	0.23

Factored in this way, the correlation coefficient stands revealed as the geometric mean of two betas and is interpreted as follows. If a causal linear relationship runs from X to Y , (i.e., if X causes Y), the logical quantity to focus on is $\beta_{Y|X}$. Likewise, if a causal linear relationship runs from Y to X , (i.e., if Y causes X), the logical quantity to focus on is $\beta_{X|Y}$.

But when we don't know which way the causation flows, or even if the relationship is linear, we throw our hands up, take the geometric mean of these two betas, and call this quantity the correlation coefficient! For jointly normally distributed random variables, the correlation coefficient fully captures and encapsulates their covariation. For all other distributions, it serves merely as a useful shortcut that measures their covariation in a standardized way, as evidenced by the fact that its value is bounded between -1 and 1 .

The application of the Theil-Sen regression to the robust estimation of correlation is now obvious. Given two random vectors, X and Y , first regress X on Y , and then regress Y on X , using the Theil-Sen regression both times. The geometric mean of the two slopes is a robust estimate of the correlation coefficient, that is,

$$\rho_{X,Y}^{\text{Robust}} = \sqrt{\beta_{Y|X}^{\text{Theil-Sen}} \times \beta_{X|Y}^{\text{Theil-Sen}}} \quad (17)$$

When the random vectors are drawn from a normal distribution and are not corrupted by noise, we expect that this approach will work

just as well as the standard maximum likelihood estimator. In the presence of outliers, or if distribution of X and Y is highly skewed, it ought to do much better. And so it is, as the data in Tables 3 and 4 demonstrate.

Table 3 compares the performance of equation (16) to the standard maximum likelihood estimator when X and Y are drawn from a normal distribution, while Table 4 performs an identical comparison for Pareto(2) random variables. Both tables are created by extending the simulations used to illuminate the performance of the Theil-Sen regression to compute correlations as well.

The results follow the pattern established in Tables 1 and 2 for the slope coefficient. When X and Y are drawn from a normal distribution, the distribution of the Theil-Sen estimate of correlation is essentially identical to that of the maximum likelihood estimate; and when they are drawn from a Pareto(2) distribution, the Theil-Sen estimate of correlation is far more stable than the maximum likelihood estimate. Similar results are obtained when either X or Y (or both) are contaminated with noise (i.e., with outliers).

It is a short step from estimating individual correlations to estimating correlation matrices, and the repeated use of the Theil-Sen estimator across a set of random variables gives us a computationally inefficient but robust estimate of a correlation matrix $\hat{\rho}$, whose i,j th element is denoted by $\hat{\rho}_{ij}$, and whose diagonal elements

Table 4 Distribution of Theil-Sen Estimates of Correlation vs. Standard Maximum Likelihood Estimate: Pareto(2) Distributed Random Variables

Percentiles	1	5	10	25	50	75	90	95	99
Theil-Sen correlation	-0.11	-0.07	-0.05	-0.03	0	0.03	0.06	0.08	0.13
Maximum Likelihood correlation	-0.15	-0.11	-0.1	-0.06	-0.02	0.04	0.12	0.19	0.37

are all 1. Unfortunately, there is no guarantee that this correlation matrix will be nonnegative definite.

This, however, is no cause for alarm. It is relatively easy to transform this matrix into a nearby nonnegative definite correlation matrix ρ^* . Ideally, the transformation will minimally distort $\hat{\rho}$, and the many available solutions to this problem differ largely in the metric (or norm) that they use to measure the distance between $\hat{\rho}$ and ρ^* . In general, they solve the following optimization problem:

$$\text{Minimize } \|\rho^* - \hat{\rho}\|, \text{ s.t. } \rho^* \text{ is a nonnegative definite correlation matrix.} \tag{18}$$

Lindskog (2000), Rousseeuw and Molenberghs (1993), and Higham (2002) describe a number of different ways in which the nearest correlation matrix can be identified using both linear and nonlinear transformations of $\hat{\rho}$. The method that seems to work best in practice is the iterative method described by Higham (2002), which iteratively identifies the closest valid correlation matrix under a Frobenius norm (the sum of squared element by element differences) by factoring the correlation matrix in a particular way, forcing its negative eigenvalues to 0, then recombining its constituent pieces and forcing its diagonal elements to 1. The algorithm is described here for the sake of completeness and can be found in the NAG Fortran and C Libraries, as well as the NAG Toolbox for Matlab.

We first define two operators, $P_S(A)$ and $P_U(A)$ that can be applied to any symmetric matrix A . As A is symmetric, it admits a spectral decomposition $A = QDQ^T$, where Q is orthogonal, and $D = \text{diag}(\lambda_i)$ is a square matrix whose diagonal elements are the eigenvalues of A , and whose off-diagonal elements are 0. $P_S(A)$ and $P_U(A)$ are defined via

$$P_S(A) = QD^*Q^T, D_{ij}^* = \max(D_{ij}, 0), \text{ and} \tag{19}$$

$$P_U(A) = \text{Set } D_{ii} = 1, \text{ i.e. replace all diagonal elements of } D \text{ by } 1. \tag{20}$$

The algorithm proceeds as follows, with both X_k and Y_k converging linearly to ρ^* :

Algorithm H (Higham, 2002)

1. $\Delta S_0 = 0, X_0 = I, Y_0 = \hat{\rho}, k = 0$
2. While $\|Y_k - X_k\| > \varepsilon$, Do
 - a. $k = k + 1$
 - b. $R_k = Y_{k-1} - \Delta S_{k-1}$ (Dykstra's correction to speed convergence)
 - c. $X_k = P_S(R_k)$
 - d. $\Delta S_k = X_k - R_k$
 - e. $Y_k = P_U(X_k)$
3. $\rho^* = Y_k$

It is but a short step from estimating a robust nonnegative definite correlation matrix to estimating a similarly robust nonnegative *definite covariance matrix*. Given robust estimates of the volatility of each security, say σ_i^{Robust} , we can form a matrix whose diagonal elements are the robust volatilities of the assets, and whose off-diagonal elements are all 0, that is,

$$\Sigma = \begin{bmatrix} \sigma_1^{Robust} & 0 & \cdot & 0 \\ 0 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & 0 \\ 0 & \cdot & 0 & \sigma_N^{Robust} \end{bmatrix} \tag{21}$$

and we can then define a robust nonnegative definite covariance matrix \hat{C} via:

$$\hat{C} = \Sigma \rho^* \Sigma \tag{22}$$

If the correlation matrix is nonnegative definite, the covariance matrix described in equation (22) is nonnegative definite as well. Rousseeuw and Croux (1993) describe a number of robust estimators of volatility, their preferred one being $Q_N(X)$, which is defined to be 2.222 times the 25th percentile of the set of distances $\{|x_i - x_j|, i < j\}$. They explore the properties of this estimator, which is similar in spirit to the Hodges-Lehmann (1963) estimate of the mean, show that its efficiency for the normal distribution is high (82%), and that it is robust to errors of arbitrary size in approximately half the points.

The *robust covariance matrix* defined by equation (22) can be used in a variety of applications such as mean-variance portfolio analysis and risk budgeting. It proves remarkably useful in practice, as it reduces and often completely eliminates the need for various constraints to ensure positive solutions that accord with a thoughtful portfolio manager's intuition.

KEY POINTS

- The Theil-Sen regression algorithm is an extraordinarily simple, intuitive, and robust algorithm for performing univariate regressions.
- The Theil-Sen estimator should be used routinely in place of OLS when performing univariate regressions, and in place of the standard maximum likelihood estimator when estimating correlations.
- The fact that the Theil-Sen estimator does not generalize naturally to multivariate regression should not be held against it—the vast majority of regressions that are carried out in practice are univariate, and a wide range of robust algorithms that work well with multivariate data are known.
- The Theil-Sen regression algorithm can be used to obtain robust estimates of beta, which can be further enhanced by the application of Dimson's correction for nonsynchronous trading and Vasicek's Bayesian adjustment.
- The robust estimates of correlation obtained from the Theil-Sen regression algorithm can be used as inputs to Higham's projection algorithm to estimate a nonnegative definite correlation matrix. This nonnegative definite correlation matrix can be combined with Rousseeuw and Croux's robust estimator of volatility to estimate a nonnegative definite covariance matrix. This nonnegative definite covariance matrix is of particular use in a wide range of mean-variance portfolio optimization and risk budgeting applications, including, but not limited to, the construction of minimum variance portfolios.

Working with High-Frequency Data

IRENE ALDRIDGE

Managing Partner, Able Alpha Trading

Abstract: High-frequency trading (HFT) has exploded into the popular press as a major development affecting securities markets around the world. Unlike more established trading approaches that examine daily data and tactically rebalance portfolios every month or quarter, HFT parses trade-by-trade data at the highest speeds available. This typically implies that high-frequency traders monitor every tick of many securities concurrently and make their portfolio allocation decisions at lightning speeds with ultra-short investment horizons in mind. In fact, hedge fund managers consider strategies to be high frequency when their holding periods range from microseconds to several hours, without any positions held overnight. To process reams of data and make informed and rational decisions at such high speeds would be difficult even for the most accomplished traders. Thankfully, computer technology has evolved to become robust and inexpensive enough to aid any willing portfolio manager to take up the high-frequency craft.

This entry examines high-frequency data, the particularities and opportunities they bring, and compares these data with their low-frequency counterparts, wherever appropriate. *High-frequency trading* (HFT) strategies by their nature use a different population of data, and the traditional methods of data analysis need to be adjusted accordingly. Specifically, this entry examines the topics of volume, time-spacing, and bid-ask-bounce inherent in the high-frequency data.

WHAT ARE HIGH-FREQUENCY DATA?

High-frequency data, also known as “tick data,” are a record of live market activity. Every time a customer, a dealer, or another entity posts a so-called limit order to buy s units of a specific

security with ticker X at price q , a bid quote $q_{t_b}^b$ is logged at time t_b to buy $s_{t_b}^b$ units of X . (Market orders are incorporated into tick data in a different way as discussed below.) When the newly arrived bid quote $q_{t_b}^b$ has the highest price relative to all other previously arrived bid quotes in force, $q_{t_b}^b$ becomes known as “the best bid” available at time t_b . Similarly, when a trading entity posts a limit order to sell s units of X at price q , an ask quote $q_{t_a}^a$ is logged at time t_a to sell $s_{t_a}^a$ units of X . If the latest $q_{t_a}^a$ is lower than all other available ask quotes for security X , $q_{t_a}^a$ becomes known as “the best ask” at time t_a .

What happens to quotes from the moment they arrive largely depends on the venue where the orders are posted. Best bids and asks posted directly on an exchange will be broadcast to all exchange participants and other parties tracking quote data. In situations when the new best

bid exceeds the best ask already in force on the exchange, $q_{t_b}^b \geq q_{t_a}^a$, most exchanges will immediately “match” such quotes, executing a trade at the preexisting best ask, $q_{t_a}^a$ at time t_b . Conversely, should the newly arrived best ask fall below the current best bid, $q_{t_a}^a \leq q_{t_b}^b$, the trade is executed at the preexisting best bid, $q_{t_b}^b$ at time t_a .

Most *dark pools* match bids and asks “crossing the spread,” but may not broadcast the newly arrived quotes (hence the mysterious moniker, the “dark pools”). Similarly, quotes destined for the interdealer networks may or may not be disseminated to other market participants, depending on the venue.

Market orders contribute to high-frequency data in the form of “last trade” information. Unlike a limit order that is an order to buy a specified quantity of a security at a certain price, a market order is an order to buy a specified quantity of a security at the best price available at the moment the order is “posted” on the trading venue. As such, market orders are executed immediately at the best available bid or best ask prices, with each market buy order executed at the best ask and each market sell matched with the best bid, and the transaction is recorded in the quote data as the “last trade price” and the “last trade size.”

A large market order may need to be matched with one or several best quotes, generating several “last trade” data points. For example, if the newly arrived market buy order is smaller in size than that of the best ask, the best ask quote may still remain in force on most trading venues, but the best ask size will be reduced to reflect that the portion of the best ask quote has been matched with the market order. When the size of the incoming market buy order is bigger than the size of the corresponding best ask, the market order consumes the best ask in its entirety, and then proceeds to be matched sequentially with the next available best ask until the size of the market order is fulfilled. The remaining lowest-priced ask quote becomes the best ask available on the trading venue.

Most limit and market orders are placed in so-called “lot sizes”: increments of a certain number of units, known as a lot. In foreign exchange, a standard trading lot today is US\$5 million, a considerable reduction from a minimum of \$25 million entertained by high-profile brokers just a few years ago. On equity exchanges, a lot can be as low as one share, but dark pools may still enforce a 100 share minimum requirement for orders. An order for the amount other than an integer increment of a lot size is called an “odd lot.”

Small limit and market “odd lot” orders posted through a broker-dealer may be aggregated, or “packaged,” by the broker-dealer into larger-size orders in order to obtain volume discounts at the orders’ execution venue. In the process, the brokers may “sit” on quotes without transmitting them to an executing venue, delaying execution of customers’ orders.

HOW ARE HIGH-FREQUENCY DATA RECORDED?

The highest-frequency data are a collection of sequential “ticks,” arrivals of the latest quote, trade, price, order size, and volume information. Tick data usually have the following properties:

- A timestamp
- A financial security identification code
- An indicator of what information it carries
- Bid price
- Ask price
- Available bid size
- Available ask size
- Last trade price
- Last trade size
- Security-specific data, such as implied volatility for options
- The market value information, such as the actual numerical value of the price, available volume, or size

A timestamp records the date and time at which the quote originated. It may be the time

at which the exchange or the broker-dealer released the quote, or the time when the trading system has received the quote. At the time this entry is written, the standard “round-trip” travel time of an order quote from the ordering customer to the exchange and back to the customer with the acknowledgement of order receipt is 15 milliseconds or less in New York. Brokers have been known to be fired by their customers if they are unable to process orders at this now standard speed. Sophisticated quotation systems, therefore, include milliseconds and even microseconds as part of their timestamps.

Another part of the quote is an identifier of the financial security. In equities, the identification code can be a ticker, or, for tickers simultaneously traded on multiple exchanges, a ticker followed by the exchange symbol. For futures, the identification code can consist of the underlying security, futures expiration date, and exchange code.

The last trade price shows the price at which the last trade in the security cleared. Last trade price can differ from the bid and ask. The differences can arise when a customer posts a favorable limit order that is immediately matched by the broker without broadcasting the customer’s quote. Last trade size shows the actual size of the last executed trade.

The best bid is the highest price available for sale of the security in the market. The best ask is the lowest price entered for buying the security at any particular time. In addition to the best bid and best ask, quotation systems may disseminate “market depth” information: the bid and ask quotes entered posted on the trading venue at prices worse than the best bid and ask, as well as aggregate order sizes corresponding to each bid and ask recorded on the trading venue’s “books.” Market depth information is sometimes referred to as the Level II data and may be disseminated as the premium subscription service only. In contrast, the best bid, best ask, last trade price, and size information (“Level I data”) is often available for a small nominal fee.

Panels (a) and (b) of Figure 1 illustrate a 30-second log of Level I high-frequency data recorded by NYSE Arca for SPDR S&P 500 ETF (ticker SPY) from 14:00:16:400 to 14:02:00:000 GMT on November 9, 2009. Panel (a) shows quote data: best bid, best ask, and last trade information, while panel (b) displays corresponding position sizes (best bid size, best ask size, and last trade size).

PROPERTIES OF HIGH-FREQUENCY DATA

High-frequency securities data have been studied for many years. Yet, the concept is still something of a novelty to many academics and practitioners. Unlike daily or monthly data sets commonly used in much of financial research and related applications, high-frequency data have distinct properties, which simultaneously can be advantageous and intimidating to researchers. Table 1 summarizes the properties of high-frequency data. Each property, its advantages, and its disadvantages are discussed in detail later in the entry.

HIGH-FREQUENCY DATA ARE VOLUMINOUS

The nearly two-minute sample of tick data for SPDR S&P 500 ETF (ticker SPY) shown in Figure 1 contained over 100 observations of Level I data: best bid quotes and sizes, best ask quotes and sizes, and last trade prices and sizes. Table 2 summarizes the breakdown of the data points provided by NYSE Arca for SPY from 14:00:16:400 to 14:02:00:000 GMT on November 9, 2009, and SPY, Japanese yen futures, and a euro call option throughout the day on November 9, 2009. Other Level I data omitted from Table 2 include cumulative daily trade volume for SPY and Japanese yen futures, and “Greeks” for the euro call option. The number of quotes observed on November 9, 2009, for SPY alone would comprise over 160 years of daily open,

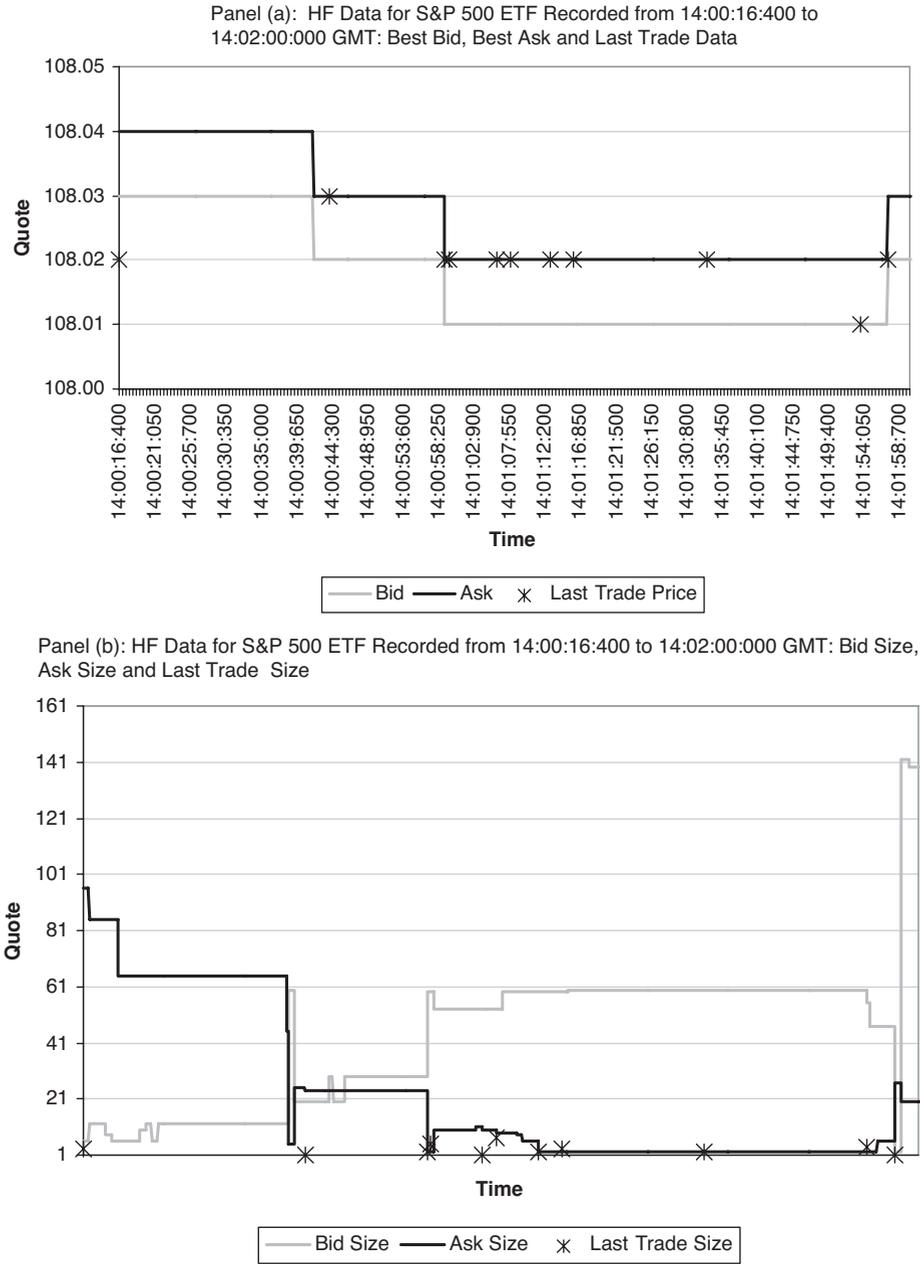

Figure 1 Level I High-Frequency Data Recorded by NYSE Arca for SPDR S&P 500 ETF (ticker SPY) from 14:00:16:400 to 14:02:00:000 GMT on November 9, 2009

high, low, close, and volume data points, assuming an average of 252 trading days per year.

The quality of data does not always match its quantity. Centralized exchanges generally provide accurate data on bids, asks, and volume of any. The information on the limit order book is less commonly available. In decentralized mar-

kets, such as foreign exchange and the inter-bank money market, no market-wide quotes are available at any given time. In such markets, participants are aware of the current price levels, but each institution quotes its own prices adjusted for its order book. In decentralized markets, each dealer provides his or her own

Table 1 Summary of Properties of High-Frequency Data

Property of HF Data	Description	Pros	Cons
Voluminous	Each day of high-frequency data contains the number of observations equivalent to 30 years of daily data.	Large numbers of observations carry lots of information.	High-frequency data are difficult to handle manually.
Irregularly spaced in time	Arrival of tick data is asynchronous.	Durations between data arrivals carry information.	Most traditional models require regularly spaced data; need to convert high-frequency data to some regular intervals, or "bars" of data. Converted data is often sparse (populated with zero returns), once again making traditional econometric inferences difficult.
Subject to bid-ask bounce	Unlike traditional data based on just closing prices, tick data carries additional supply and demand information in the form of bid and ask prices and offering sizes.	Bid and ask quotes can carry valuable information about impending market moves and can be harnessed to researcher's advantage.	Bid and ask quotes are separated by a spread. Continuous movement from bid to ask and back introduces a jump process, difficult to deal with through many conventional models.

tick data to clients. As a result, a specific quote on a given financial instrument at any given time may vary from dealer to dealer. Reuters, Telerate, and Knight Ridder, among others, collect quotes from different dealers and disseminate them back, improving the efficiency of the decentralized markets.

There are generally thought to be three anomalies in interdealer quote discrepancies. First, each dealer's quotes reflect that dealer's own inventory. For example, a dealer that has just sold a customer \$100 million of USD/CAD would be eager to diversify the risk of the posi-

tion and avoid selling any more of USD/CAD. Most dealers are, however, obligated to transact with their clients on tradable quotes. To incite clients to place sell orders on USD/CAD, the dealer temporarily raises the bid quote on USD/CAD. At the same time, to encourage clients to withhold placing buy orders, the dealer raises the ask quote on USD/CAD. Thus, dealers tend to raise both bid and ask prices whenever they are short in a particular financial instrument and lower both bid and ask prices whenever they are disproportionally long in a financial instrument.

Table 2 Summary Statistics for Level I Quotes for Selected Securities on November 9, 2009

Quote Type	SPY, 14:00:16:400 to 14:02:00:000 GMT	SPY, all day	USD/JPY Dec 2009 Futures, all day	EUR/USD Call Expiring Dec 2009 with Strike Price of 1.5100, all day
Best Bid Quote	4 (3%)	5,467 (3%)	6,320 (5%)	1,521 (3%)
Best Bid Size	36 (29%)	38,948 (19%)	39,070 (32%)	5,722 (11%)
Best Ask Quote	4 (3%)	4,998 (2%)	6,344 (5%)	1,515 (3%)
Best Ask Size	35 (28%)	38,721 (19%)	38,855 (32%)	5,615 (11%)
Last Trade Price	6 (5%)	9,803 (5%)	3,353 (3%)	14 (0%)
Last Trade Size	20 (16%)	27,750 (14%)	10,178 (8%)	25 (0%)
Total	125	203,792	123,216	49,982

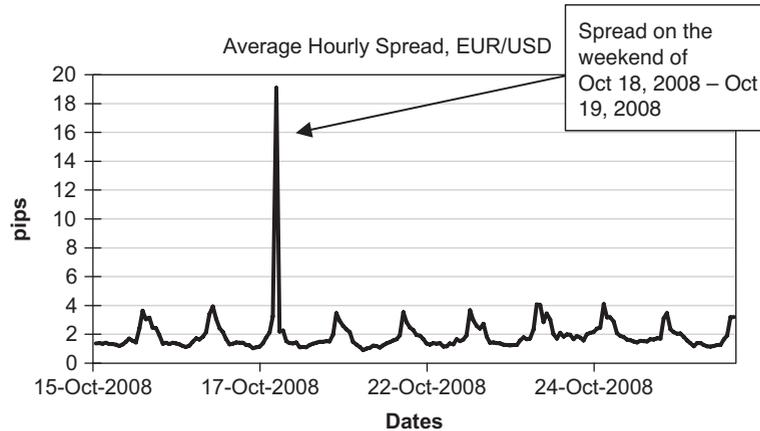

Figure 2 Average Hourly Bid-Ask Spread on EUR/USD Spot for the Last Two Weeks of October 2008 on a Median Transaction Size of USD 5 million
Source: Aldridge (2009).

Second, in an anonymous marketplace, such as a dark pool, dealers as well as other market makers may “fish” for market information by sending indicative quotes that are much off the previously quoted price to assess the available demand or supply.

Third, Dacorogna et al. (2001) note that some dealers’ quotes may lag real market prices. The lag is thought to vary from milliseconds to a minute. Some dealers quote moving averages of quotes of other dealers. The dealers who provide delayed quotes usually do so to advertise their market presence in the data feed. This was particularly true when most order prices were negotiated over the telephone, allowing a considerable delay between quotes and orders. Fast-paced electronic markets discourage lagged quotes, improving the quality of markets.

HIGH-FREQUENCY DATA ARE SUBJECT TO BID-ASK BOUNCE

In addition to trade price and volume data long available in low-frequency formats, high-frequency data comprise bid and ask quotes and the associated order sizes. Bid and ask data

arrive asynchronously and introduce noise in the quote process.

The difference between the bid quote and the ask quote at any given time is known as the bid-ask spread. The bid-ask spread is the cost of instantaneously buying and selling the security. The higher the bid-ask spread, the higher a gain the security must produce in order to cover the spread along with other transaction costs. Most low-frequency price changes are large enough to make the bid-ask spread negligible in comparison. In tick data, on the other hand, incremental price changes can be comparable or smaller than the bid-ask spread.

Bid-ask spreads usually vary throughout the day. Figure 2 illustrates the average bid-ask spread cycles observed in the institutional EUR/USD market for the last two weeks of October 2008. As Figure 2 shows, the average spread increases significantly during Tokyo trading hours when the market is quiet. The spread then reaches its lowest levels during the overlap of the London and New York trading sessions when the market has many active buyers and sellers. The spike in the spread over the weekend of October 18–19, 2008, reflects the market concern over the subpoenas issued on October 17, 2009, to senior Lehman executives

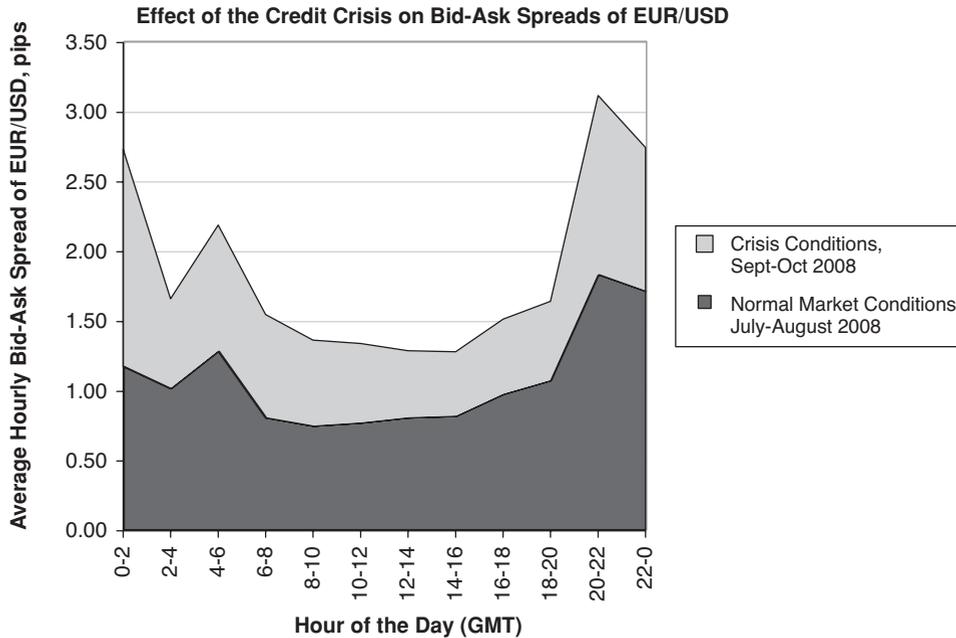

Figure 3 Comparison of Average Bid-Ask Spreads for Different Hours of the Day during Normal Market Conditions and Crisis Conditions

in a case relating to potential securities fraud at Lehman Brothers.

Bid-ask spreads typically increase during periods of market uncertainty or instability. Figure 3, for example, compares average bid-ask spreads on EUR/USD in the stable market conditions of July–August 2008 and the crisis conditions of September–October 2008. As the figure shows, the intraday spread pattern is persistent in both crisis and normal market conditions, but the spreads are significantly higher during crisis months than during normal conditions at all hours of the day. As Figure 3 also shows, the spread increase is not uniform at all hours of the day. The average hourly EUR/USD spreads increased by 0.0048% (0.48 basis points or pips) between the hours of 12 GMT and 16 GMT, when the London and New York trading sessions overlap. From 0 to 2 GMT, during the Tokyo trading hours, the spread increased by 0.0156%, over three times the average increase during the New York/London hours.

As a result of increasing bid-ask spreads during periods of uncertainty and crises, the

profitability of high-frequency strategies decreases during those times. For example, high-frequency EUR/USD strategies running over Asian hours incurred significantly higher costs during September and October 2008 as compared with normal market conditions. A strategy that executed 100 trades during Asian hours alone resulted in 1.56 percent evaporating from daily profits due to the increased spreads, while the same strategy running during London and New York hours resulted in a smaller but still significant daily profit decrease of 0.48%. The situation can be even more severe for high-frequency strategies built for less liquid instruments. For example, bid-ask spreads for NZD/USD (not shown) on average increased thrice during September–October in comparison with market conditions of July–August 2008.

While tick data carries information about market dynamics, it is also distorted by the same processes that make the data so valuable in the first place. Dacorogna et al. (2001) report that sequential trade price bounces between the

bid and ask quotes during market execution of orders introduce significant distortions into estimation of high-frequency parameters. Corsi, Zumbach, Muller, and Dacorogna (2001), for example, show that the bid-ask bounce introduces a considerable bias into volatility estimates. The authors calculate that the bid-ask bounce on average results in -40% negative first-order autocorrelation of tick data. Corsi et al. (2001) as well as Voev and Lunde (2007) propose to remedy the bias by filtering the data from the bid-ask bounce prior to estimation.

To use standard econometric techniques in the presence of the bid-ask bounce, many practitioners convert the tick data to "mid-quote" format: the simple average of the latest bid and ask quotes. The mid-quote is used to approximate the price level at which the market is theoretically willing to trade if buyers and sellers agreed to meet each other halfway on the price spectrum. Mathematically, the mid-quote can be expressed as follows:

$$\hat{q}_{t_m}^m = \frac{1}{2} (q_{t_a}^a + q_{t_b}^b) \text{ where } t_m = \begin{cases} t_a, & \text{if } t_a \geq t_b \\ t_b, & \text{otherwise} \end{cases} \quad (1)$$

The latter condition for t_m reflects the continuous updating of the mid-quote estimate: $\hat{q}_{t_m}^m$ is updated whenever the latest best bid, $q_{t_b}^b$, or best ask quote, $q_{t_a}^a$, arrives, at t_b or t_a respectively.

Another way to sample tick quotes into a cohesive data series is by weighing the latest best bid and best ask quotes by their accompanying order sizes:

$$\tilde{q}_t^s = \frac{q_{t_b}^b s_{t_a}^a + q_{t_a}^a s_{t_b}^b}{s_{t_a}^a + s_{t_b}^b} \quad (2)$$

where $q_{t_b}^b$ and $s_{t_b}^b$ is the best bid quote and the best bid available size recorded at time t_b (when $q_{t_b}^b$ became the best bid), and $q_{t_a}^a$ and $s_{t_a}^a$ is the best ask quote and the best ask available size recorded at time t_a .

Figure 5 compares the histograms of simple returns computed from mid-quote (panel a), size-weighted mid-quote (panel b), and trade-price (panel c) processes for SPDR S&P 500 ETF data recorded as they arrive throughout

November 9, 2009. The data neglect the time difference between the adjacent quotes, treating each sequential quote as an independent observation. Figure 6 contrasts the quantile distribution plots of the same data sets with the quantiles of a standard normal distribution.

As Figures 4 and 5 show, the basic mid-quote distribution is constrained by the minimum "step size": The minimum changes in the mid-quote can occur at half-tick increments (at present, the minimum tick size is \$0.01 in equities). The size-weighted mid-quote forms the most continuous distribution among the three distributions discussed. Figure 6 confirms this notion further and also illustrates the fat tails present in all three types of data distributions.

In addition to real-time adjustments to bid-ask data, researchers deploy forecasting techniques to estimate the impending bid-ask spread and adjust for it in models ahead of time. Future realizations of the bid-ask spread can be estimated using the model suggested by Roll (1984), where the price of an asset at time t , p_t , is assumed to equal an unobservable fundamental value, m_t , offset by a value equal to half of the bid-ask spread, s . The price offset is positive when the next market order is a buy, and negative when the trade is a sell, as shown in equation (3):

$$p_t = m_t + \frac{s}{2} I_t \quad (3)$$

$$\text{where } I_t = \begin{cases} 1, & \text{market buy at ask} \\ -1, & \text{market sell at bid} \end{cases}$$

If either a buy or a sell order can arrive next with equal probability, then $E[I_t] = 0$, and $E[\Delta p_t] = 0$, absent changes in the fundamental asset value, m_t . The covariance of subsequent price changes, however, is different from 0:

$$\text{cov}[\Delta p_t, \Delta p_{t+1}] = E[\Delta p_t \Delta p_{t+1}] = -\frac{s^2}{4} \quad (4)$$

As a result, the future expected spread can be estimated as follows:

$$E[s] = 2\sqrt{-\text{cov}[\Delta p_t, \Delta p_{t+1}]} \text{ whenever } \text{cov}[\Delta p_t, \Delta p_{t+1}] < 0$$

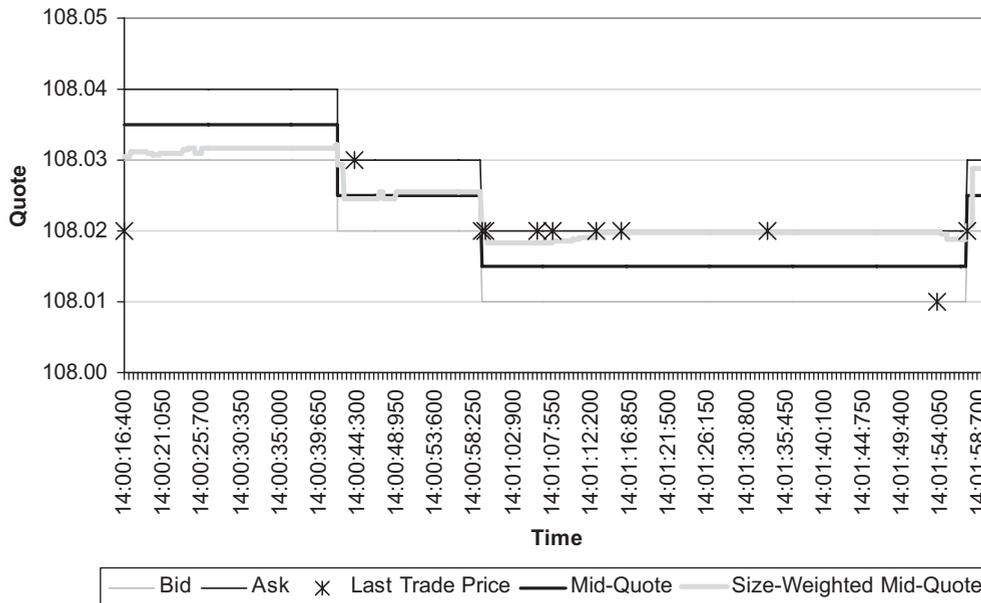

Figure 4 Bid-Ask Aggregation Techniques on Data for SPDR S&P 500 ETF (ticker SPY) Recorded by NYSE Arca on November 9, 2009, from 14:00:16:400 to 14:00:02:000 GMT

Numerous extensions of Roll's model have been developed to account for contemporary market conditions along with numerous other variables. Hasbrouck (2007) provides a good summary of the models.

HIGH-FREQUENCY DATA ARE IRREGULARLY SPACED IN TIME

Most modern computational techniques have been developed to work with regularly spaced data, presented in monthly, weekly, daily, hourly, or other consistent intervals. The traditional reliance of researchers on fixed time intervals is due to:

- Relative availability of daily data (newspapers have published daily quotes since the 1920s).
- Relative ease of processing regularly spaced data.
- An outdated view that “whatever drove security prices and returns, it probably did not vary significantly over short time intervals.” (Goodhart and O’Hara, 1997, pp. 80–81)

In contrast, high-frequency observations are separated by varying time intervals. One way to overcome the irregularities in the data is to sample it at certain predetermined periods of time—for example, every hour or minute. For example, if the data are to be converted from tick data to minute “bars,” then under the traditional approach, the bid or ask price for any given minute would be determined as the last quote that arrived during that particular minute. If no quotes arrived during a certain minute, then the previous minute’s closing prices would be taken as the current minute’s closing prices, and so on. Figure 7, panel (a) illustrates this idea. This approach implicitly assumes that in the absence of new quotes, the prices stay constant, which does not have to be the case.

Dacorogna et al. (2001) propose a potentially more precise way to sample quotes—linear time-weighted interpolation between adjacent quotes. At the core of the interpolation technique is an assumption that at any given time, unobserved quotes lie on a straight line that connects two neighboring observed quotes.

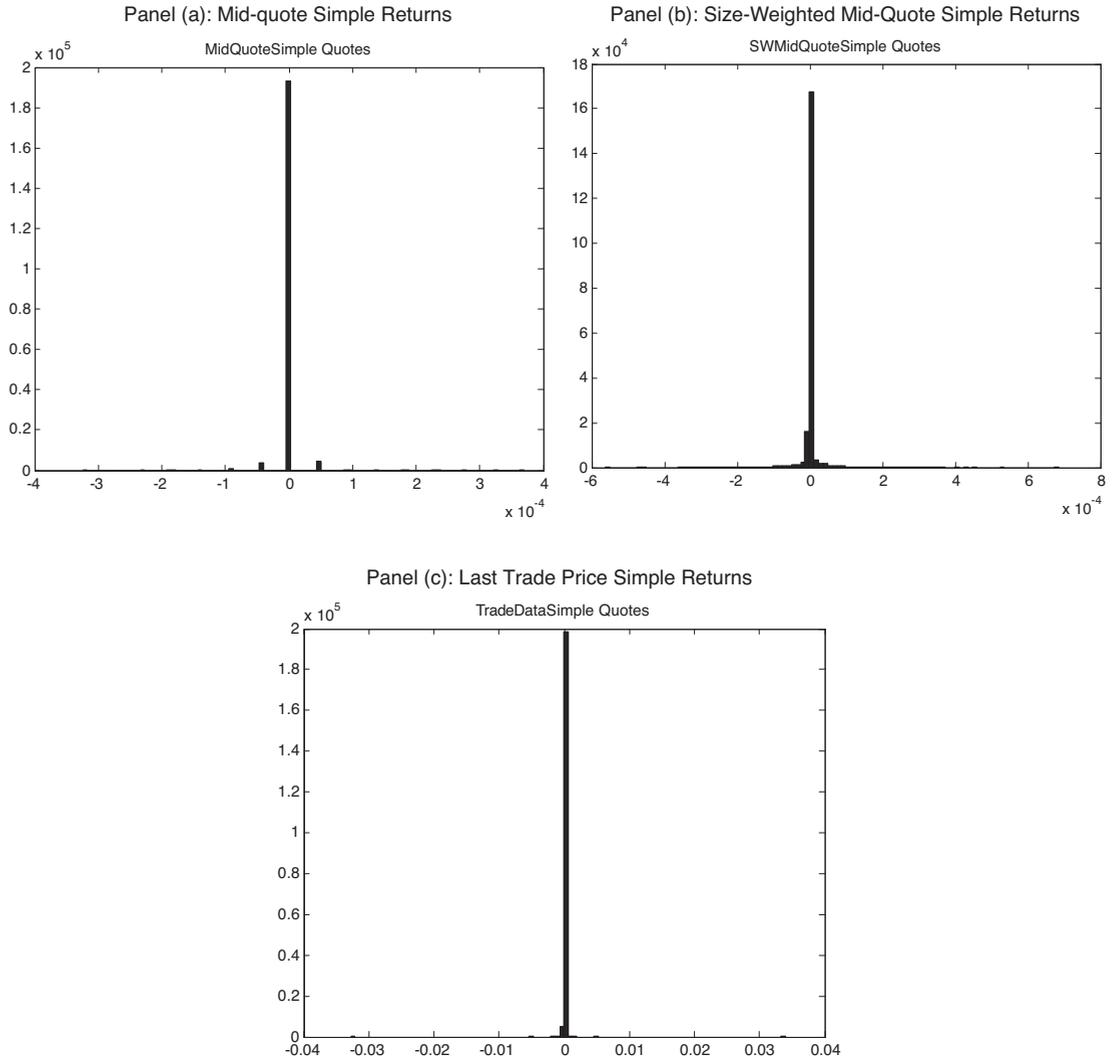

Figure 5 Histograms of Simple Returns Computed from Mid-Quote (panel a), Size-Weighted Mid-Quote (panel b), and Trade-Price (panel c) Processes for SPDR S&P 500 ETF Data Recorded as They Arrive Throughout November 9, 2009

Figure 7, panel (b) illustrates linear interpolation sampling.

As shown in Figure 7, panels (a) and (b), the two quote-sampling methods produce quite different results.

Mathematically, the two sampling methods can be expressed as follows:

Quote sampling using closing prices: $\hat{q}_t = q_{t,last}$ (5)

Quote sampling using linear interpolation:

$$\hat{q}_t = q_{t,last} + (q_{t,next} - q_{t,last}) \frac{t - t_{last}}{t_{next} - t_{last}} \quad (6)$$

where \hat{q}_t is the resulting sampled quote, t is the desired sampling time (start of a new minute, for example), t_{last} is the timestamp of the last observed quote prior to the sampling time t , $q_{t,last}$ is the value of the last quote prior to the sampling time t , t_{next} is the timestamp of the first observed quote after the sampling time t ,

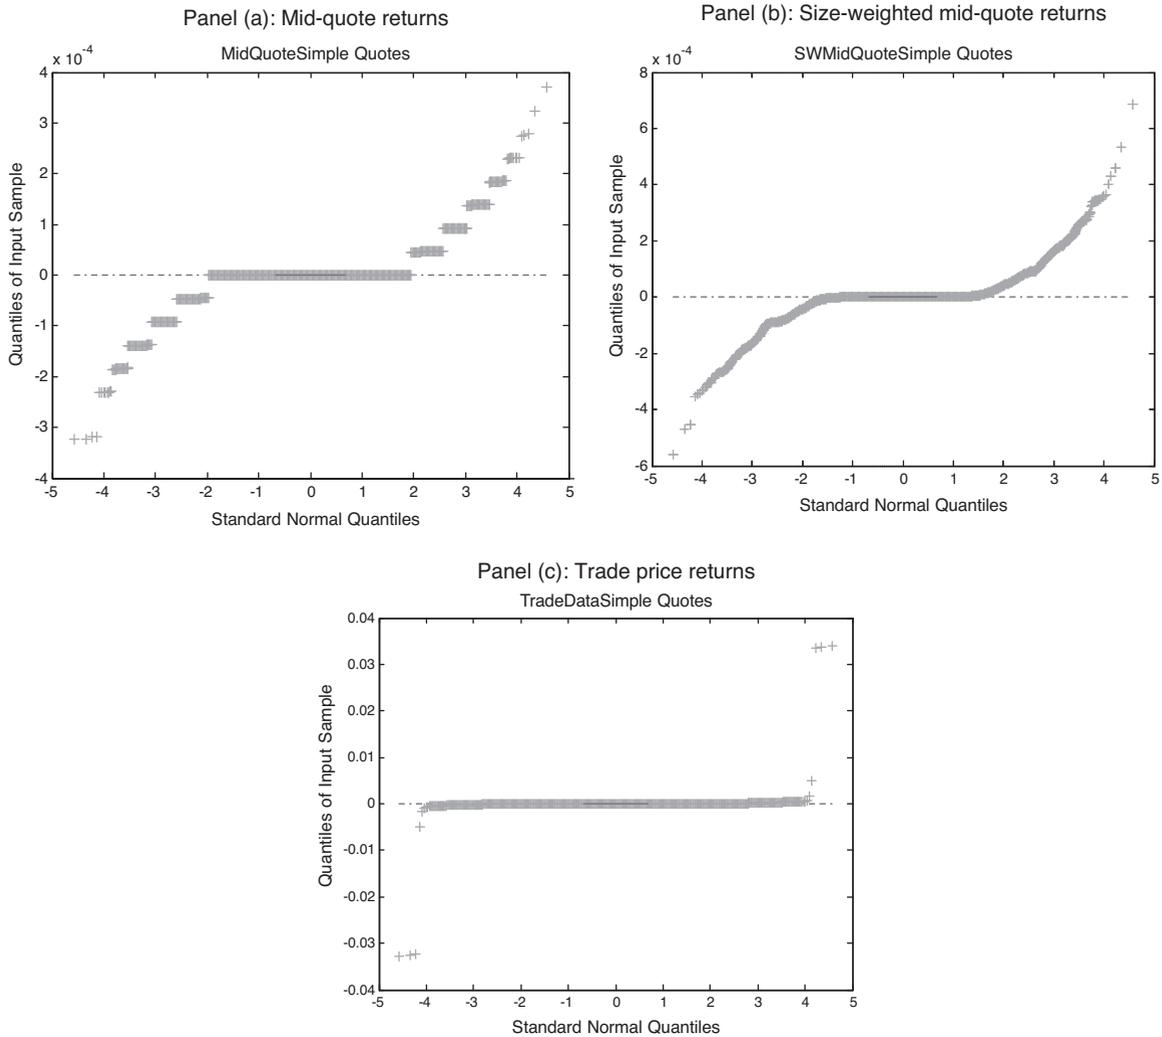

Figure 6 Quantile Plots of Simple Returns of Mid-Quote (panel a), Size-Weighted Mid-Quote (panel b), and Trade-Price (panel c) Processes for SPDR S&P 500 ETF Data Recorded as They Arrive Throughout November 9, 2009

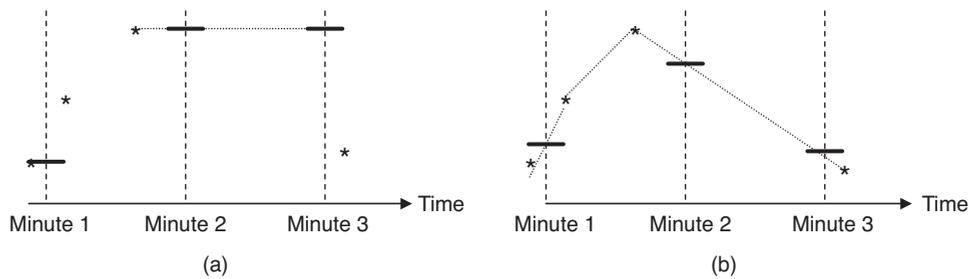

Figure 7 Data-Sampling Methodologies

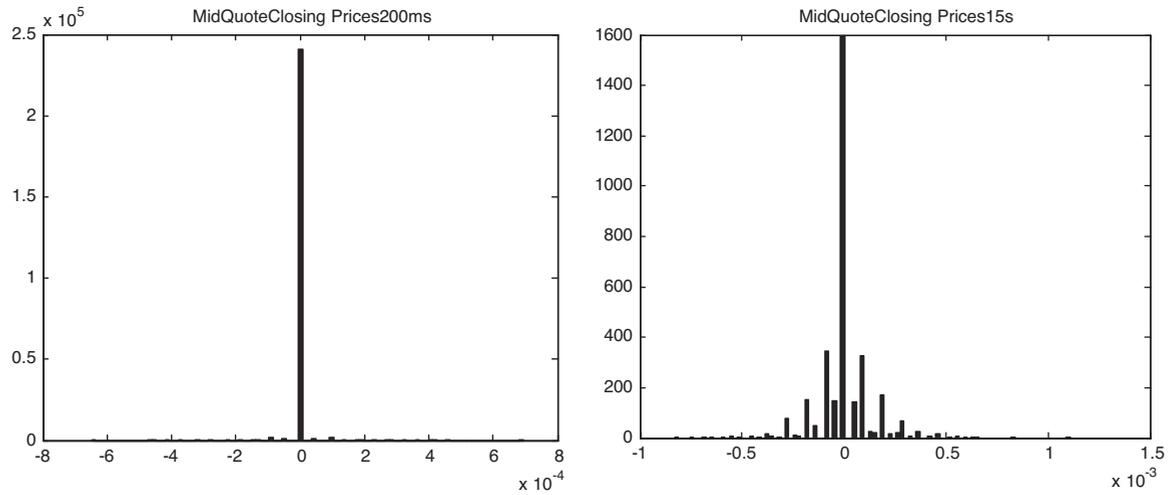

Figure 8 Mid-Quote “Closing Quotes” Sampled at 200 ms (left) and 15s Intervals

and $q_{t,next}$ is the value of the first quote after the sampling time t .

Figures 8 and 9 compare histograms of the mid-quote data sampled as closing prices and interpolated at frequencies of 200 ms and 15s. Figure 10 compares quantile plots of closing prices and interpolated distributions. As Figures 8 and 9 show, often-sampled distributions are sparse, that is, contain more 0 returns than distributions sampled at lower frequencies. At the same time, returns computed from interpo-

lated quotes are more continuous than closing prices, as Figure 10 illustrates.

Instead of manipulating the interquote intervals into the convenient regularly spaced formats, several researchers have studied whether the time distance between subsequent quote arrivals itself carries information. For example, most researchers agree that intertrade intervals indeed carry information on securities for which short sales are disallowed; the lower the *intertrade duration*, the more likely the

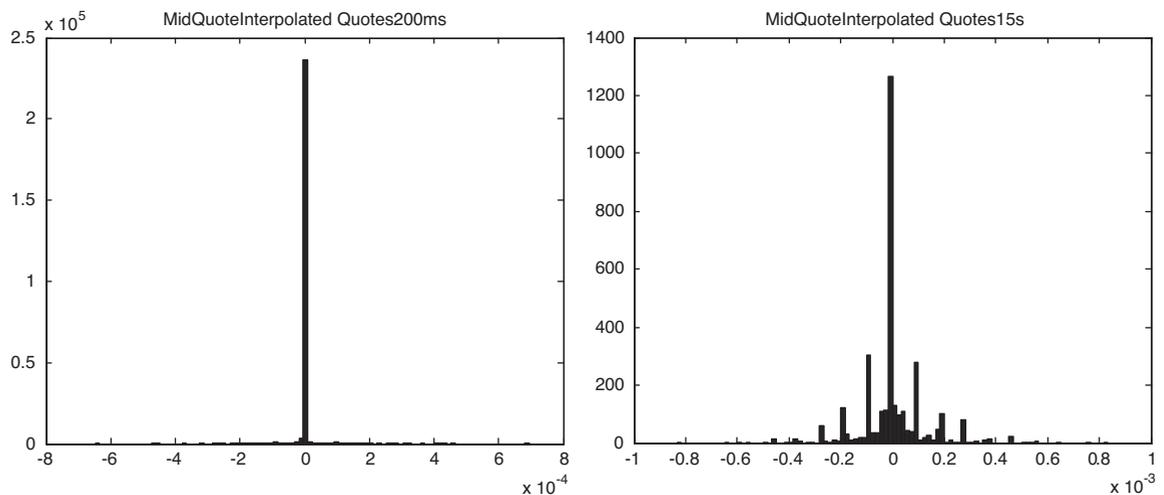

Figure 9 Mid-Quote “Time-Interpolated Quotes” Sampled at 200 ms (left) and 15s Intervals

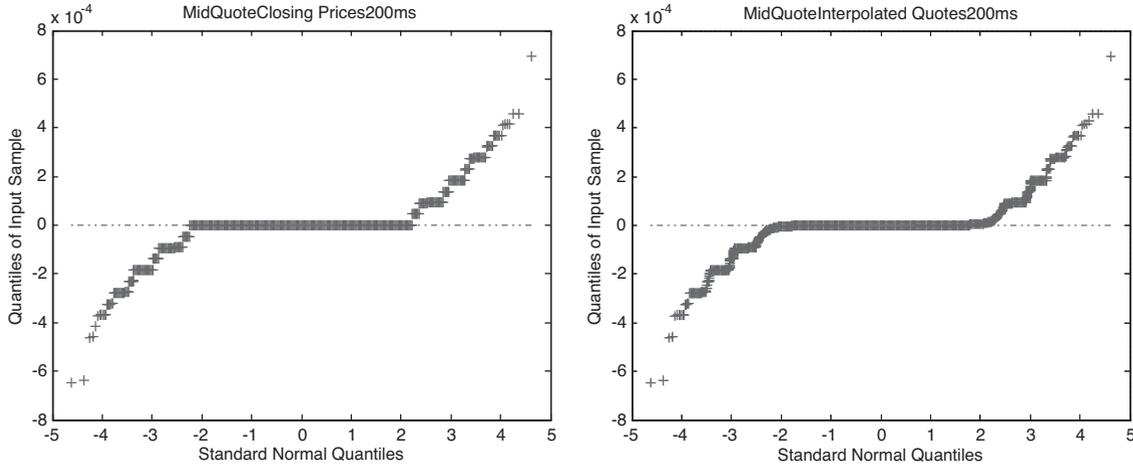

Figure 10 Quantile Plots: Closing Prices vs. Interpolated Mid-Quotes Sampled at 200 ms

yet-to-be-observed good news and the higher the impending price change.

Duration models are used to estimate the factors affecting the time between any two sequential ticks. Such models are known as quote processes and trade processes, respectively. Duration models are also used to measure the time elapsed between price changes of a prespecified size, as well as the time interval between predetermined trade volume increments. The models working with fixed price are known as price processes; the models estimating variation in duration of fixed volume increments are known as volume processes.

Durations are often modeled using *Poisson processes* that assume that sequential events, like quote arrivals, occur independently of one another. The number of arrivals between any two time points t and $(t + \tau)$ is assumed to have a Poisson distribution. In a Poisson process, λ arrivals occur per unit time. In other words, the arrivals occur at an average rate of $(1/\lambda)$. The average arrival rate may be assumed to hold constant, or it may vary with time. If the average arrival rate is constant, the probability of observing exactly k arrivals between times t and $(t + \tau)$ is

$$P[(N(t + \tau) - N(t)) = k] = \frac{1}{k!} e^{-\lambda\tau} (\lambda\tau)^k, \quad k = 0, 1, 2, \dots \quad (7)$$

Diamond and Verrecchia (1987) and Easley and O'Hara (1992) were the first to suggest that the duration between subsequent ticks carries information. Their models posit that in the presence of short-sale constraints, intertrade duration can indicate the presence of good news; in markets of securities where short selling is disallowed, the shorter the intertrade duration, the higher is the likelihood of unobserved good news. The reverse also holds: In markets with limited short selling and normal liquidity levels, the longer the duration between subsequent trade arrivals, the higher the probability of yet-unobserved bad news. A complete absence of trades, however, indicates a lack of news.

Easley and O'Hara (1992) further point out that trades that are separated by a time interval have a much different information content than trades occurring in close proximity. One of the implications of Easley and O'Hara (1992) is that the entire price sequence conveys information and should be used in its entirety whenever possible, strengthening the argument for high-frequency trading.

Table 3 shows summary statistics for a duration measure computed on all trades recorded for S&P 500 Depository Receipts ETF (SPY) on May 13, 2009. As Table 3 illustrates, the average intertrade duration was the longest outside of

regular market hours, and the shortest during the hour preceding the market close (3–4 P.M. ET).

The variation in duration between subsequent trades may be due to several other causes. While the lack of trading may be due to a lack of new information, trading inactivity may also be due to low levels of liquidity, trading halts on exchanges, and strategic motivations of traders. Foucault, Kadan, and Kandel (2005) consider that patiently providing liquidity using limit orders may itself be a profitable trading strategy, as liquidity providers should be compensated for their waiting. The compensation usually comes in the form of a bid-ask spread and is a function of the waiting time until the order limit is “hit” by liquidity takers; lower intertrade durations induce lower spreads. However, Dufour and Engle (2000) and Saar and Hasbrouck (2002) find that spreads are actually higher when traders observe short durations, contrasting the time-based limit order compensation hypothesis.

In addition to durations between subsequent trades and quotes, researchers have also been modeling durations between fixed changes in security prices and volumes. The time interval between subsequent price changes of a spec-

ified magnitude is known as price duration. Price duration has been shown to decrease with increases in volatility. Similarly, the time interval between subsequent volume changes of a prespecified size is known as the volume duration. Volume duration has been shown to decrease with increases in liquidity.

The information content of quote, trade, price, and volume durations introduces biases into the estimation process, however. If the available information determines the time between subsequent trades, time itself ceases to be an independent variable, introducing substantial endogeneity bias into estimation. As a result, traditional estimates of variance of transaction prices are too high in comparison with the true variance of the price series.

KEY POINTS

- High-frequency data are different from daily or lower frequency data. Whereas low frequency data typically comprise regularly spaced open, high, low, close, and volume information for a given financial security recorded during a specific period of time, high-frequency data include bid and ask quotes, sizes, and latest trade characteristics

that are recorded sequentially at irregular time intervals.

- The differences affect trading strategy modeling, introducing new opportunities and pitfalls for researchers.
- Numerous data points allow researchers to deduce statistically significant inferences on even short samples of high-frequency data.
- Different sampling approaches have been developed to convert high-frequency data into a more regular format better familiar to researchers, yet diverse sampling methodologies result in datasets with drastically dissimilar statistical properties.
- Some properties of high-frequency data, like intertrade duration, carry important market information unavailable at lower frequencies.

Financial Modeling Principles

Milestones in Financial Modeling

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: The origins of financial modeling can be traced back to the development of mathematical equilibrium at the end of the nineteenth century, followed in the beginning of the twentieth century with the introduction of sophisticated mathematical tools for dealing with the uncertainty of prices and returns. In the 1950s and 1960s, financial modelers had tools for dealing with probabilistic models for describing markets, the principles of contingent claims analysis, an optimization framework for portfolio selection based on mean and variance of asset returns, and an equilibrium model for pricing capital assets. The 1970s ushered in models for pricing contingent claims and a new model for pricing capital assets based on arbitrage pricing. Consequently, by the end of the 1970s, the frameworks for financial modeling were well known. It was the advancement of computing power and refinements of the theories to take into account real-world markets starting in the 1980s that facilitated implementation and broader acceptance of mathematical modeling of financial decisions.

The mathematical development of present-day economic and finance theory began in Lausanne, Switzerland at the end of the nineteenth century, with the development of the mathematical equilibrium theory by Leon Walras (1874) and Vilfredo Pareto (1906). Shortly thereafter, at the beginning of the twentieth century, Louis Bachelier (1900) in Paris and Filip Lundberg (1903) in Uppsala (Sweden) made two seminal contributions: They developed sophisticated mathematical tools to describe uncertain price and risk processes. These developments were well in advance of their time. Further progress was to be made only much later in the twentieth century, thanks to the de-

velopment of digital computers. By making it possible to compute approximate solutions to complex problems, digital computers enabled the large-scale application of mathematics to business problems.

A first round of innovation occurred in the 1950s and 1960s. Kenneth Arrow and Georges Debreu (1954) introduced a probabilistic model of markets and the notion of contingent claims. Harry Markowitz (1952) described mathematically the principles of the investment process in terms of utility optimization. In 1961, Franco Modigliani and Merton Miller (1961) clarified the nature of economic value, working out the implications of absence of arbitrage. Between

1964 and 1966, William Sharpe (1964), John Lintner (1965), and Jan Mossin (1966) developed a theoretical model of market prices based on the principles of financial decision making laid down by Markowitz. The notion of efficient markets was introduced by Paul Samuelson (1965), and five years later, further developed by Eugene Fama (1970).

The second round of innovation started at the end of the 1970s. In 1973, Fischer Black, Myron Scholes (1973), and Robert Merton (1973a) discovered how to determine option prices using continuous hedging. Three years later, Stephen Ross (1976) introduced arbitrage pricing theory (APT). Both were major developments that were to result in a comprehensive mathematical methodology for investment management and the valuation of derivative financial products. At about the same time, Merton introduced a continuous-time intertemporal, dynamic optimization model of asset allocation. Major refinements in the methodology of mathematical optimization and new econometric tools were to change the way investments are managed.

More recently, the diffusion of electronic transactions has made available a huge amount of empirical data. The availability of this data created the hope that economics could be given a more solid scientific grounding. A new field—econophysics—opened with the expectation that the proven methods of the physical sciences and the newly born science of complex systems could be applied with benefit to economics. It was hypothesized that economic systems could be studied as physical systems with only minimal a priori economic assumptions. Classical econometrics is based on a similar approach; but while the scope of classical econometrics is limited to dynamic models of time series, econophysics uses all the tools of statistical physics and complex systems analysis, including the theory of interacting multi-agent systems.

In this entry, we will describe the milestones in financial modeling.

THE PRECURSORS: PARETO, WALRAS, AND THE LAUSANNE SCHOOL

The idea of formulating quantitative laws of economic behavior in ways similar to the physical sciences started in earnest at the end of the 19th century. Though quite accurate economic accounting on a large scale dates back to Assyro-Babylonian times, a scientific approach to economics is a recent endeavor.

Leon Walras and Wilfredo Pareto, founders of the so-called Lausanne School at the University of Lausanne in Switzerland, were among the first to explicitly formulate quantitative principles of market economies, stating the principle of economic equilibrium as a mathematical theory. Both worked at a time of great social and economic change. In Pareto's work in particular, pure economics and political science occupy a central place.

Convinced that economics should become a mathematical science, Walras set himself the task of writing the first mathematical general equilibrium system. The British economist Stanley Jevons and the Austrian economist Carl Menger had already formulated the idea of economic equilibrium as a situation where supply and demand match in interrelated markets. Walras's objective—to prove that equilibrium was indeed possible—required the explicit formulation of the equations of supply-and-demand equilibrium.

Walras introduced the idea of *tatonnement* (French for groping) as a process of exploration by which a central auctioneer determines equilibrium prices. A century before, in 1776, Adam Smith had introduced the notion of the "invisible hand" that coordinates the activity of independent competitive agents to achieve desirable global goals. In the modern parlance of complex systems, the "invisible hand" would be called an "emerging property" of competitive markets. Much recent work on complex systems and artificial life has focused

on understanding how the local interaction of individuals might result in complex and purposeful global behavior. Walras was to make the hand “visible” by defining the process of price discovery.

Pareto followed Walras in the Chair of Economics at the University of Lausanne. Pareto’s focus was the process of economic decision making. He replaced the idea of supply-and-demand equilibrium with a more general idea of the ordering of preferences through utility functions. (Pareto used the word “ophelimity” to designate what we would now call utility. The concept of ophelimity is slightly different from the concept of utility insofar as ophelimity includes constraints on people’s preferences.) Equilibrium is reached where marginal utilities are zero. The Pareto system hypothesized that agents are able to order their preferences and take into account constraints in such a way that a numerical index—“utility” in today’s terminology—can be associated with each choice. Note that it was not until 1944 that utility theory was formalized in a set of necessary and sufficient axioms by von Neumann and Morgenstern and applied to decision making under risk and uncertainty.

Economic decision making is therefore based on the maximization of utility. As Pareto assumed utility to be a differentiable function, global equilibrium is reached where marginal utilities (i.e., the partial derivatives of utility) vanish. Pareto was especially interested in the problem of the global optimum of utility. The Pareto optimum is a state in which nobody can be better off without making others worse off. A Pareto optimum does not imply the equal division of resources; quite the contrary, a Pareto optimum might be a maximally unequal distribution of wealth.

A lasting contribution of Pareto is the formulation of a law of income distribution. Known as the *Pareto law*, this law states that there is a linear relationship between the logarithm of the income I and the number N of people that earn

more than this income:

$$\text{Log } N = A + s \log I$$

where A and s are appropriate constants.

The importance of the works of Walras and Pareto were not appreciated at the time. Without digital computers, the equilibrium systems they conceived were purely abstract: There was no way to compute solutions to economic equilibrium problems. In addition, the climate at the turn of the century did not allow a serene evaluation of the scientific merit of their work. The idea of free markets was at the center of heated political debates; competing systems included mercantile economies based on trade restrictions and privileges as well as the emerging centrally planned Marxist economies.

PRICE DIFFUSION: BACHELIER

In 1900, the Sorbonne University student Louis Bachelier presented a doctoral dissertation, *Théorie de la Spéculation*, that was to anticipate much of today’s work in finance theory. Bachelier’s advisor was the great French mathematician Henri Poincaré. There were three notable aspects in Bachelier’s thesis: (1) He argued that in a purely speculative market stock prices should be random; (2) he developed the mathematics of Brownian motion; and (3) he computed the prices of several options.

To appreciate the importance of Bachelier’s work, it should be remarked that at the beginning of the 20th century, the notion of probability was not yet rigorous; the formal mathematical theory of probability was developed only in the 1930s. In particular, the precise notion of the propagation of information essential for the definition of conditional probabilities in continuous time had not yet been formulated.

Anticipating the development of the theory of efficient markets 60 years later, the key economic idea of Bachelier was that asset prices in a speculative market should be a fair game, that

is, a martingale process such that the expected return is zero. According to Bachelier, "The expectation of the speculator is zero." The formal concept of a martingale (i.e., of a process such that its expected value at any moment coincides with the present value) had not yet been introduced in probability theory. In fact, the rigorous notion of conditional probability and filtration were developed only in the 1930s. In formulating his hypothesis on market behavior, Bachelier relied on intuition.

Bachelier actually went much further. He assumed that stock prices evolve as a continuous-time Markov process. This was a brilliant intuition: Markov was to start working on these problems only in 1906. Bachelier established the differential equation for the time evolution of the probability distribution of prices, noting that this equation was the same as the heat diffusion equation. Five years later, in 1905, Albert Einstein used the same diffusion equation for the Brownian motion (i.e., the motion of a small particle suspended in a fluid). Bachelier also made the connection with the continuous limit of random walks, thus anticipating the work of the Japanese mathematician Kiyosi Ito at the end of the 1940s and the Russian mathematician and physicist Ruslan Stratonovich on stochastic integrals at the end of the 1950s.

By computing the extremes of Brownian motion, Bachelier computed the price of several options. He also computed the distributions of a number of functionals of Brownian motion. These were remarkable mathematical results in themselves. Formal proof was given only much later. Even more remarkable, Bachelier established option pricing formulas well before the formal notion of absence of arbitrage was formulated.

Bachelier's work was outside the mainstream of contemporary mathematics but was too mathematically complex for the economists of his time. It wasn't until the formal development of probability theory in 1930s that his ideas became mainstream mathematics and only in the 1960s, with the development of the theory of

efficient markets, that his ideas became part of mainstream finance theory. In an efficient market, asset prices should, in each instant, reflect all the information available at the time, and any event that causes prices to move must be unexpected (i.e., a random disturbance). As a consequence, prices move as martingales, as argued by Bachelier. Bachelier was, in fact, the first to give a precise mathematical structure in continuous time to price processes subject to competitive pressure by many agents.

THE RUIN PROBLEM IN INSURANCE: LUNDBERG

In Uppsala, Sweden, in 1903, three years after Bachelier defended his doctoral dissertation in Paris, Filip Lundberg defended a thesis that was to become a milestone in actuarial mathematics: He was the first to define a collective theory of risk and to apply a sophisticated probabilistic formulation to the insurance ruin problem. The ruin problem of an insurance company in a non-life sector can be defined as follows. Suppose that an insurance company receives a stream of sure payments (premiums) and is subject to claims of random size that occur at random times. What is the probability that the insurer will not be able to meet its obligations (i.e., the probability of ruin)?

Lundberg solved the problem as a collective risk problem, pooling together the risk of claims. To define collective risk processes, he introduced marked Poisson processes. Marked Poisson processes are processes where the random time between two events is exponentially distributed. The magnitude of events is random with a distribution independent of the time of the event. Based on this representation, Lundberg computed an estimate of the probability of ruin.

Lundberg's work anticipated many future developments of probability theory, including what was later to be known as the *theory of point processes*. In the 1930s, the Swedish mathematician and probabilist Harald Cramer

gave a rigorous mathematical formulation to Lundberg's work. A more comprehensive formal theory of insurance risk was later developed. This theory now includes Cox processes—point processes more general than Poisson processes—and fat-tailed distributions of claim size.

A strong connection between actuarial mathematics and asset pricing theory has since been established. (See, for example, Embrechts, Klüppelberg, and Mikosch, 1996). In well-behaved, complete markets, establishing insurance premiums entails principles that mirror asset prices. In the presence of complete markets, insurance would be a risk-free business: There is always the possibility of reinsurance. In markets that are not complete—essentially because they make unpredictable jumps—hedging is not possible; risk can only be diversified and options are inherently risky. Option pricing theory again mirrors the setting of insurance premiums.

Lundberg's work went unnoticed by the actuarial community for nearly 30 years, though this did not stop him from enjoying a successful career as an insurer. Both Bachelier and Lundberg were in advance of their time; they anticipated, and probably inspired, the subsequent development of probability theory. But the type of mathematics implied by their work could not be employed in full earnest prior to the development of digital computers. It was only with digital computers that we were able to tackle complex mathematical problems whose solutions go beyond closed-form formulas.

THE PRINCIPLES OF INVESTMENT: MARKOWITZ

Just how an investor should allocate his resources has long been debated. Classical wisdom suggested that investments should be allocated to those assets yielding the highest returns, without the consideration of correlations. Before the modern formulation of efficient markets, speculators widely acted on the

belief that positions should be taken only if they had a competitive advantage in terms of information. A large amount of resources were therefore spent on analyzing financial information. John Maynard Keynes suggested that investors should carefully evaluate all available information and then make a calculated bet. The idea of diversification was anathema to Keynes, who was actually quite a successful investor.

In 1952, Harry Markowitz, then a graduate student at the University of Chicago, published a seminal article on optimal portfolio selection that upset established wisdom. He advocated that, being risk adverse, investors should diversify their portfolios. (The principles in his article were developed further in his 1959 book.) The idea of making risk bearable through risk diversification was not new: It was widely used by medieval merchants. Markowitz understood that the risk-return trade-off of investments could be improved by diversification and cast diversification in the framework of optimization.

Markowitz was interested in the investment decision-making process. Along the lines set forth by Pareto 60 years earlier, Markowitz assumed that investors order their preferences according to a *utility index*, with utility as a convex function that takes into account investors' risk-return preferences. Markowitz assumed that stock returns are jointly normal. As a consequence, the return of any portfolio is a normal distribution, which can be characterized by two parameters: the mean and the variance. Utility functions are therefore defined on two variables—mean and variance—and the Markowitz framework for portfolio selection is commonly referred to as *mean-variance analysis*. The mean and variance of portfolio returns are in turn a function of a portfolio's weights. Given the variance-covariance matrix, utility is a function of portfolio weights. The investment decision-making process involves maximizing utility in the space of portfolio weights.

The inputs to the mean-variance analysis include expected returns, variance of returns, and

either covariance or correlation of returns between each pair of securities. For example, an analysis that allows 200 securities as possible candidates for portfolio selection requires 200 expected returns, 200 variances of return, and 19,900 correlations or covariances. An investment team tracking 200 securities may reasonably be expected to summarize their analyses in terms of 200 means and variances, but it is clearly unreasonable for them to produce 19,900 carefully considered correlation coefficients or covariances. It was clear to Markowitz that some kind of model of the covariance structure was needed for the practical application of the model. He did little more than point out the problem and suggest some possible models of covariance for research to large portfolios. In 1963, William Sharpe suggested the single index market model as a proxy for the covariance structure of security returns.

Markowitz joined the Rand Corporation, where he met George Dantzig, who introduced him to computer-based optimization technology. Markowitz was quick to appreciate the role that computers would have in bringing mathematics to bear on business problems. Optimization and simulation were on the way to becoming the tools of the future, replacing the quest for closed-form solutions of mathematical problems.

In the following years, Markowitz developed a full theory of the investment management process based on optimization. His optimization theory had the merit of being applicable to practical problems, even outside of the realm of finance. With the progressive diffusion of high-speed computers, the practice of financial optimization has found broad application.

UNDERSTANDING VALUE: MODIGLIANI AND MILLER

At about the same time that Markowitz was tackling the problem of how investors should behave, taking asset price processes as a given, other economists were trying to understand

how markets determine value. Adam Smith had introduced the notion of perfect competition (and therefore perfect markets) in the second half of the 18th century. In a perfect market, there are no impediments to trading: Agents are price takers who can buy or sell as many units as they wish. The neoclassical economists of the 1960s took the idea of perfect markets as a useful idealization of real free markets. In particular, they argued that financial markets are very close to being perfect markets. The theory of asset pricing was subsequently developed to explain how prices are set in a perfect market.

In general, a *perfect market* results when the number of buyers and sellers is sufficiently large, and all participants are small enough relative to the market so that no individual market agent can influence a commodity's price. Consequently, all buyers and sellers are price takers, and the market price is determined where there is equality of supply and demand. This condition is more likely to be satisfied if the commodity traded is fairly homogeneous (for example, corn or wheat).

There is more to a perfect market than market agents being price takers. It is also required that there are no transaction costs or impediments that interfere with the supply and demand of the commodity. Economists refer to these various costs and impediments as "frictions."

The costs associated with frictions generally result in buyers paying more than in the absence of frictions, and/or sellers receiving less. In the case of financial markets, frictions include:

- Commissions charged by brokers.
- Bid-ask spreads charged by dealers.
- Order handling and clearance charges.
- Taxes (notably on capital gains) and government-imposed transfer fees.
- Costs of acquiring information about the financial asset.
- Trading restrictions, such as exchange-imposed restrictions on the size of a position in the financial asset that a buyer or seller may take.

- Restrictions on market makers.
- Halts to trading that may be imposed by regulators where the financial asset is traded.

Modigliani-Miller Irrelevance Theorems and the Absence of Arbitrage

A major step was taken in 1958 when Franco Modigliani and Merton Miller published a then-controversial article in which they maintained that the value of a company does not depend on the capital structure of the firm. (In a 1963 article, they corrected their analysis for the impact of corporate taxes.) The capital structure is the mix of debt and equity used to finance the firm. The traditional view prior to the publication of the article by Modigliani and Miller was that there existed a capital structure that maximized the value of the firm (i.e., there is an optimal capital structure). Modigliani and Miller demonstrated that in the absence of taxes and in a perfect capital market, the capital structure was irrelevant (i.e., the capital structure does not affect the value of a firm). By extension, the irrelevance principle applies to the type of debt a firm may select (e.g., senior, subordinated, secured, and unsecured).

In 1961, Modigliani and Miller published yet another controversial article in which they argued that the value of a company does not depend on the dividends it pays but on its earnings. The basis for valuing a firm—earnings or dividends—had always attracted considerable attention. Because dividends provide the hard cash that remunerates investors, they were considered by many as key to a firm's value.

Modigliani and Miller's challenge to the traditional view that capital structure and dividends matter when determining a firm's value was founded on the principle that the traditional views were inconsistent with the workings of competitive markets where securities are freely traded. In their view, the value of a company is independent of its financial structure: From a valuation standpoint, it does not mat-

ter whether the firm keeps its earnings or distributes them to shareholders.

Known as the *Modigliani-Miller theorems*, these theorems paved the way for the development of arbitrage pricing theory. In fact, to establish their theorems, Modigliani and Miller made use of the notion of *absence of arbitrage*. Absence of arbitrage means that there is no possibility of making a risk-free profit without an investment. This implies that the same stream of cash flows should be priced in the same way across different markets. Absence of arbitrage is the fundamental principle for relative asset pricing; it is the pillar on which derivative pricing rests.

EFFICIENT MARKETS: FAMA AND SAMUELSON

Absence of arbitrage entails market efficiency. Shortly after the Modigliani-Miller theorems had been established, Paul Samuelson in 1965 and Eugene Fama in 1970 developed the notion of efficient markets: A market is efficient if prices reflect all available information. Bachelier had argued that prices in a competitive market should be random conditionally to the present state of affairs. Fama and Samuelson put this concept into a theoretical framework, linking prices to information.

In general, an *efficient market* refers to a market where prices at all times fully reflect all available information that is relevant to the valuation of securities. That is, relevant information about the security is quickly impounded into the price of securities.

Fama and Samuelson define "fully reflects" in terms of the expected return from holding a security. The expected return over some holding period is equal to expected cash distributions plus the expected price change, all divided by the initial price. The price formation process defined by Fama and Samuelson is that the expected return one period from now is a stochastic variable that already takes into account the "relevant" information set. They argued that in a market where information is shared by

all market participants, prices should fluctuate randomly.

A price-efficient market has implications for the investment strategy that investors may wish to pursue. In an active strategy, investors seek to capitalize on what they perceive to be the mispricing of financial instruments (cash instruments or derivative instruments). In a market that is price efficient, active strategies will not consistently generate a return after taking into consideration transaction costs and the risks associated with a strategy that is greater than simply buying and holding securities. This has led investors in certain sectors of the capital market where empirical evidence suggests the sector is price efficient to pursue a strategy of indexing, which simply seeks to match the performance of some financial index. However Samuelson was careful to remark that the notion of efficient markets does not make investment analysis useless; rather, it is a condition for efficient markets.

Another facet in this apparent contradiction of the pursuit of active strategies despite empirical evidence on market efficiency was soon to be clarified. Agents optimize a risk-return trade-off based on the stochastic features of price processes. Price processes are not simply random but exhibit a rich stochastic behavior. The objective of investment analysis is to reveal this behavior.

CAPITAL ASSET PRICING MODEL: SHARPE, LINTNER, AND MOSSIN

Absence of arbitrage is a powerful economic principle for establishing relative pricing. In itself, however, it is not a market equilibrium model. William Sharpe (1964), John Lintner (1965), and Jan Mossin (1966) developed a theoretical equilibrium model of market prices called the *capital asset pricing model* (CAPM). As anticipated 60 years earlier by Walras and Pareto, Sharpe, Lintner, and Mossin developed

the consequences of Markowitz's portfolio selection into a full-fledged stochastic general equilibrium theory.

Asset pricing models categorize risk factors into two types. The first type is risk factors that cannot be diversified away via the Markowitz framework. That is, no matter what the investor does, the investor cannot eliminate these risk factors. These risk factors are referred to as *systematic risk factors* or *nondiversifiable risk factors*. The second type is risk factors that can be eliminated via diversification. These risk factors are unique to the asset and are referred to as *unsystematic risk factors* or *diversifiable risk factors*.

The CAPM has only one systematic risk factor—the risk of the overall movement of the market. This risk factor is referred to as “market risk.” This is the risk associated with holding a portfolio consisting of all assets, called the “market portfolio.” In the market portfolio, an asset is held in proportion to its market value. So, for example, if the total market value of all assets is \$ X and the market value of asset j is \$ Y , then asset j will comprise \$ Y /\$ X of the market portfolio.

The expected return for an asset i according to the CAPM is equal to the risk-free rate plus a risk premium. The risk premium is the product of (1) the sensitivity of the return of asset i to the return of the market portfolio, and (2) the difference between the expected return on the market portfolio and the risk-free rate. It measures the potential reward for taking on the risk of the market above what can be earned by investing in an asset that offers a risk-free rate. Taken together, the risk premium is a product of the quantity of market risk and the potential compensation of taking on market risk (as measured by the second component).

The CAPM was highly appealing from the theoretical point of view. It was the first general-equilibrium model of a market that admitted testing with econometric tools. A critical challenge to the empirical testing of the CAPM as pointed out by Roll (1977) is the identification of the market portfolio.

THE MULTIFACTOR CAPM: MERTON

The CAPM assumes that the only risk that an investor is concerned with is uncertainty about the future price of a security. Investors, however, are usually concerned with other risks that will affect their ability to consume goods and services in the future. Three examples would be the risks associated with future labor income, the future relative prices of consumer goods, and future investment opportunities.

Recognizing these other risks that investors face, Robert Merton (1973b) extended the CAPM based on consumers deriving their optimal lifetime consumption when they face these “extramarket” sources of risk. These extramarket sources of risk are also referred to as “factors,” hence the model derived by Merton is called a multifactor CAPM.

The multifactor CAPM says that investors want to be compensated for the risk associated with each source of extramarket risk, in addition to market risk. In the case of the CAPM, investors hedge the uncertainty associated with future security prices by diversifying. This is done by holding the market portfolio. In the multifactor CAPM, in addition to investing in the market portfolio, investors will also allocate funds to something equivalent to a mutual fund that hedges a particular extramarket risk. While not all investors are concerned with the same sources of extramarket risk, those that are concerned with a specific extramarket risk will basically hedge them in the same way.

The multifactor CAPM is an attractive model because it recognizes nonmarket risks. The pricing of an asset by the marketplace, then, must reflect risk premiums to compensate for these extramarket risks. Unfortunately, it may be difficult to identify all the extramarket risks and to value each of these risks empirically. Furthermore, when these risks are taken together, the multifactor CAPM begins to resemble the arbitrage pricing theory model described next.

ARBITRAGE PRICING THEORY: ROSS

An alternative to the equilibrium asset pricing model just discussed, an asset pricing model based purely on arbitrage arguments, was derived by Stephen Ross (1976). The model, called the *arbitrage pricing theory (APT) model*, postulates that an asset’s expected return is influenced by a variety of risk factors, as opposed to just market risk as assumed by the CAPM. The APT model states that the return on a security is linearly related to H systematic risk factors. However, the APT model does not specify what the systematic risk factors are, but it is assumed that the relationship between asset returns and the risk factors is linear.

The APT model as given asserts that investors want to be compensated for all the risk factors that systematically affect the return of a security. The compensation is the sum of the products of each risk factor’s systematic risk and the risk premium assigned to it by the capital market.

Proponents of the APT model argue that it has several major advantages over the CAPM. First, it makes less restrictive assumptions about investor preferences toward risk and return. As explained earlier, the CAPM theory assumes investors trade off between risk and return solely on the basis of the expected returns and standard deviations of prospective investments. The APT model, in contrast, simply requires that some rather unobtrusive bounds be placed on potential investor utility functions. Second, no assumptions are made about the distribution of asset returns. Finally, since the APT model does not rely on the identification of the true market portfolio, the theory is potentially testable. The model simply assumes that no arbitrage is possible. That is, using no additional funds (wealth) and without increasing risk, it is not possible for an investor to create a portfolio to increase return.

The APT model provides theoretical support for an asset pricing model where there is more than one risk factor. Consequently, models of

this type are referred to as multifactor risk models. These models are applied to portfolio management.

ARBITRAGE, HEDGING, AND OPTION THEORY: BLACK, SCHOLES, AND MERTON

The idea of arbitrage pricing can be extended to any price process. A general model of asset pricing will include a number of independent price processes plus a number of price processes that depend on the first process by arbitrage. The entire pricing structure may or may not be cast in a general equilibrium framework.

Arbitrage pricing allowed derivative pricing. With the development of derivatives trading, the requirement of a derivative valuation and pricing model made itself felt. The first formal solution of the option pricing model was developed independently by Fisher Black and Myron Scholes (1973), working together, and in the same year by Robert Merton (1973a).

The solution of the option pricing problem proposed by Black, Scholes, and Merton was simple and elegant. Suppose that a market contains a risk-free bond, a stock, and an option. Suppose also that the market is arbitrage-free and that stock price processes follow a continuous-time geometric Brownian motion. Black, Scholes, and Merton demonstrated that it is possible to construct a portfolio made up of the stock plus the bond that perfectly replicates the option. The replicating portfolio can be exactly determined, without anticipation, solving a partial differential equation.

The idea of replicating portfolios has important consequences. Whenever a financial instrument (security or derivative instrument) process can be exactly replicated by a portfolio of other securities, absence of arbitrage requires that the price of the original financial instrument coincide with the price of the replicating portfolio. Most derivative pricing algorithms are based on this principle: To price a deriva-

tive instrument, one must identify a replicating portfolio whose price is known.

Pricing by portfolio replication received a powerful boost with the discovery that calculations can be performed in a risk-neutral probability space where processes assume a simplified form. The foundation was thus laid for the notion of *equivalent martingales*, developed by Michael Harrison and David Kreps (1979) and Michael Harrison and Stanley Pliska (1981). Not all price processes can be reduced in this way: If price processes do not behave sufficiently well (i.e., if the risk does not vanish with the vanishing time interval), then replicating portfolios cannot be found. In these cases, risk can be minimized but not hedged.

KEY POINTS

- The development of mathematical finance began at the end of the nineteenth century with work on general equilibrium theory by Walras and Pareto.
- At the beginning of the twentieth century, Bachelier and Lundberg made a seminal contribution, introducing respectively Brownian motion price processes and Markov Poisson processes for collective risk events.
- The advent of digital computers enabled the large-scale application of advanced mathematics to finance theory, ushering in optimization and simulation.
- In 1952, Markowitz introduced the theory of portfolio optimization, which advocates the strategy of portfolio diversification.
- In 1961, Modigliani and Miller argued that the value of a company is based not on its dividends and capital structure, but on its earnings; their formulation was to be called the Modigliani-Miller theorem.
- In the 1960s, major developments included the efficient market hypothesis (Samuelson and Fama), the capital asset pricing model (Sharpe, Lintner, and Mossin), and the multifactor CAPM (Merton).

- In the 1970s, major developments included the arbitrage pricing theory (Ross) that led to multifactor models and option pricing formulas (Black, Scholes, and Merton) based on replicating portfolios, which are used to price derivatives if the underlying price processes are known.

From Art to Financial Modeling

SERGIO M. FOCARDI, PhD

Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: It is often said that investment management is an art, not a science. However, since the early 1990s the market has witnessed a progressive shift toward a more industrial view of the investment management process. There are several reasons for this change. First, with globalization the universe of investable assets has grown many times over. Asset managers might have to choose from among several thousand possible investments from around the globe. The S&P 500 index is itself chosen from a pool of 8,000 investable U.S. stocks. Second, institutional investors, often together with their investment consultants, have encouraged asset management firms to adopt an increasingly structured process with documented steps and measurable results. Pressure from regulators and the media is another factor. Lastly, the sheer size of the markets makes it imperative to adopt safe and repeatable methodologies. The volumes are staggering.

In its modern sense, financial modeling is the design (or engineering) of contracts and portfolios of contracts that result in predetermined cash flows contingent on different events. Broadly speaking, financial models are employed to manage investment portfolios and risk. The objective is the transfer of risk from one entity to another via appropriate contracts. Though the aggregate risk is a quantity that cannot be altered, risk can be transferred if there is a willing counterparty.

Financial modeling came to the forefront of finance in the 1980s with the broad diffusion of derivative instruments. However, the concept and practice of financial modeling are quite old. Evidence of the use of sophisticated cross-border instruments of credit and pay-

ment dating from the time of the First Crusade (1095–1099) has come down to us from the letters of Jewish merchants in Cairo. The notion of the diversification of risk (central to modern risk management) and the quantification of insurance risk (a requisite for pricing insurance policies) were already understood, at least in practical terms, in the 14th century. The rich epistolary of Francesco Datini, a 14th-century merchant, banker, and insurer from Prato (Tuscany, Italy), contains detailed instructions to his agents on how to diversify risk and insure cargo. It also gives us an idea of insurance costs: Datini charged 3.5% to insure a cargo of wool from Malaga to Pisa and 8% to insure a cargo of malmsey (sweet wine) from Genoa to Southampton, England. These, according to

one of Datini's agents, were low rates: He considered 12–15% a fair insurance premium for similar cargo.

What is specific to modern financial modeling is the quantitative management of risk. Both the pricing of contracts and the optimization of investments require some basic capabilities of statistical modeling of financial contingencies. It is the size, diversity, and efficiency of modern competitive markets that makes the use of modeling imperative.

THE ROLE OF INFORMATION TECHNOLOGY

Advances in information technology are behind the widespread adoption of modeling in finance. The most important advance has been the enormous increase in the amount of computing power, concurrent with a steep fall in prices. Government agencies have long been using computers for economic modeling, but private firms found it economically justifiable only as of the 1980s. Back then, economic modeling was considered one of the "Grand Challenges" of computational science (a term coined by Kenneth Wilson [1989], recipient of the 1982 Nobel Prize in Physics, and later adopted by the U.S. Department of Energy in its High Performance Communications and Computing Program, which included economic modeling among the grand challenges).

In the late 1980s, firms such as Merrill Lynch began to acquire supercomputers to perform derivative pricing computations. The overall cost of these supercomputing facilities, in the range of several million dollars, limited their diffusion to the largest firms. Today, computational facilities ten times more powerful cost only a few thousand dollars. To place today's computing power in perspective, consider that a 1990 run-of-the-mill Cray supercomputer cost several million U.S. dollars and had a clock cycle of 4 nanoseconds (i.e., 4 billionths of a second or 250 million cycles per second, notated as 250 MHz). Today's fast laptop

computers are 10 times faster with a clock cycle of 2.5 GHz and, at a few thousand dollars, cost only a fraction of the price. Supercomputer performance has itself improved significantly, with top computing speed in the range of several teraflops compared to the several megaflops of a Cray supercomputer in the 1990s. (Flops, which stands for floating point operations per second, is a measure of computational speed. A teraflop computer is a computer able to perform a trillion floating point operations per second.) In the space of 15 years, sheer performance has increased 1,000 times while the price-performance ratio has decreased by a factor of 10,000. Storage capacity has followed similar dynamics.

The diffusion of low-cost, high-performance computers has allowed the broad use of numerical methods. Computations that were once performed by supercomputers in air-conditioned rooms are now routinely performed on desktop machines. This has changed the landscape of financial modeling. The importance of finding closed-form solutions and the consequent search for simple models has been dramatically reduced. Computationally intensive methods such as Monte Carlo simulations and the numerical solution of differential equations are now widely used. As a consequence, it has become feasible to represent prices and returns with relatively complex models. *Non-normal probability distributions* have become commonplace in many sectors of financial modeling. It is fair to say that the key limitation of financial econometrics is now the size of available data samples or training sets, not the computations; it is the data that limit the complexity of estimates.

Mathematical modeling has also undergone major changes. Techniques such as equivalent martingale methods are being used in derivative pricing and cointegration, the theory of fat-tailed processes, and state-space modeling (including ARCH/GARCH and stochastic volatility models) are being used in econometrics.

Powerful specialized mathematical languages and vast statistical software libraries have been developed. The ability to program sequences of statistical operations within a single programming language has been a big step forward. Software firms such as Mathematica and Mathworks, and major suppliers of statistical tools such as SAS, have created simple computer languages for the programming of complex sequences of statistical operations. This ability is key to financial econometrics, which entails the analysis of large portfolios. (Note that although a number of highly sophisticated statistical packages are available to economists, these packages do not serve the needs of the financial econometrician who has to analyze a large number of time series.)

Presently only large or specialized firms write complex applications from scratch; this is typically done to solve specific problems, often in the derivatives area. The majority of financial modelers make use of high-level software programming tools and statistical libraries. It is difficult to overestimate the advantage brought by these software tools; they cut development time and costs by orders of magnitude.

In addition, there is a wide range of off-the-shelf financial applications that can be used directly by operators who have a general understanding of the problem but no advanced statistical or mathematical training. For example, powerful complete applications from firms such as MSCI Barra and component applications from firms such as FEA make sophisticated analytical methods available to a large number of professionals.

Data have, however, remained a significant expense. The diffusion of electronic transactions has made available large amounts of data, including high-frequency data (HFD), which gives us information at the transaction level. As a result, in budgeting for financial modeling, data have become an important factor in deciding whether to undertake a new modeling effort.

A lot of data are now available free on the Internet. If the required granularity of data is not high, these data allow one to study the viability of models and to perform rough tuning. However, real-life applications, especially applications based on finely grained data, require data streams of a higher quality than those typically available free on the Internet.

INTEGRATING QUALITATIVE AND QUANTITATIVE INFORMATION

Textual information has remained largely outside the domain of *quantitative modeling*, having long been considered the domain of judgment. This is now changing as financial firms begin to tackle the problem of what is commonly called *information overload*; advances in computer technology are again behind the change (see Jonas and Focardi, 2002). Reuters publishes the equivalent of three bibles of (mostly financial) news daily; it is estimated that five new research documents come out of Wall Street every minute; asset managers at medium-sized firms report receiving up to 1,000 e-mails daily and work with as many as five screens on their desk. Conversely, there is also a lack of “digested” information. It has been estimated that only one third of the roughly 10,000 U.S. public companies are covered by meaningful Wall Street research; there are thousands of companies quoted on the U.S. exchanges with no Wall Street research at all. It is unlikely the situation is better relative to the tens of thousands of firms quoted on other exchanges throughout the world. Yet increasingly companies are providing information, including press releases and financial results, on their Web sites.

Such *unstructured (textual) information* is progressively being transformed into self-describing, *semistructured information* that can be automatically categorized and searched by

computers. A number of developments are making this possible. These include:

- The development of XML (eXtensible Markup Language) standards for tagging textual data. This is taking us from free text search to queries on semistructured data.
- The development of RDF (Resource Description Framework) standards for appending metadata. This provides a description of the content of documents.
- The development of algorithms and software that generate taxonomies and perform automatic categorization and indexation.
- The development of database query functions with a high level of expressive power.
- The development of high-level text mining functionality that allows “discovery.”

The emergence of standards for the handling of “meaning” is a major development. It implies that unstructured textual information, which some estimates put at 80% of all content stored in computers, will be largely replaced by semistructured information ready for machine handling at a semantic level. Today’s standard structured databases store data in a prespecified format so that the position of all elementary information is known. For example, in a trading transaction, the date, the amount exchanged, the names of the stocks traded, and so on are all stored in predefined fields. However, textual data such as news or research reports do not allow such a strict structuring. To enable the computer to handle such information, a descriptive metafile is appended to each unstructured file. The descriptive metafile is a structured file that contains the description of the key information stored in the unstructured data. The result is a semistructured database made up of unstructured data plus descriptive metafiles.

Industry-specific and application-specific standards are being developed around the general-purpose XML. At the time of this writing, there are numerous initiatives established with the objective of defining XML standards for applications in finance, from time series to

analyst and corporate reports and news. While it is not yet clear which of the competing efforts will emerge as the de facto standards, attempts are now being made to coordinate standardization efforts, eventually adopting the ISO 15022 central data repository as an integration point.

Technology for handling unstructured data has already made its way into the industry. Factiva, a Dow Jones-Reuters company, uses commercially available text mining software to automatically code and categorize more than 400,000 news items daily, in real time (prior to adopting the software, they manually coded and categorized some 50,000 news articles daily). Users can search the Factiva database, which covers 118 countries and includes some 8,000 publications and more than 30,000 company reports with simple intuitive queries expressed in a language close to the natural language. Several firms use text mining technology in their Web-based research portals for clients on the buy and sell sides. Such services typically offer classification, indexation, tagging, filtering, navigation, and search.

These technologies are helping to organize research flows. They allow us to automatically aggregate, sort, and simplify information and provide the tools to compare and analyze the information. In serving to pull together material from myriad sources, these technologies will not only form the basis of an internal knowledge management system but allow us to better structure the whole investment management process. Ultimately, the goal is to integrate data and text mining in applications such as fundamental research and event analysis, linking news, and financial time series.

PRINCIPLES FOR ENGINEERING A SUITE OF MODELS

Creating a suite of models to satisfy the needs of a financial firm is engineering in full earnest. It begins with a clear statement of the objectives.

In the case of financial modeling, the objective is identified by the type of decision-making process that a firm wants to implement. The engineering of a suite of financial models requires that the process on which decisions are made is fully specified and that the appropriate information is supplied at every step. This statement is not as banal as it might seem.

We have now reached the stage where, in some markets, financial decision making can be completely automated through optimizers. As we will see in the following entries, one can define models able to construct a conditional probability distribution of returns. An optimizer will then translate the forecast into a tradable portfolio. The manager becomes a kind of high-level supervisor of an otherwise automated process.

However, not all financial decision-making applications are, or can be, fully automated. In many cases, it is the human operator who makes the decision, with models supplying the information needed to arrive at the decision. Building an effective suite of financial models requires explicit decisions as to (1) what level of automation is feasible and desirable, and (2) what information or knowledge is required.

The integration of different models and of qualitative and quantitative information is a fundamental need. This calls for integration of different statistical measures and points of view. For example, an asset management firm might want to complement a portfolio optimization methodology based on Gaussian forecasting with a risk management process based on extreme value theory. The two processes offer complementary views. In many cases, however, different methodologies give different

results though they work on similar principles and use the same data. In these cases, integration is delicate and might run against statistical principles.

In deciding which modeling efforts to invest in, many firms have in place a sophisticated evaluation system. Firms evaluate a model's return on investment and how much it will cost to buy the data necessary to run the model.

KEY POINTS

- Key to a quantitative framework is the measurement and management of uncertainty (i.e., risk) and financial modeling.
- Modeling is the tool to achieve these objectives; advances in information technology are the enabler.
- Unstructured textual information is progressively being transformed into self-describing, semistructured information, allowing a better structuring of the research process.
- After nearly two decades of experience with quantitative methods, market participants now more clearly perceive the benefits and the limits of modeling; given today's technology and markets, the need to better integrate qualitative and quantitative information is clearly felt.

Abstract: We are confronted with data every day, constantly. Daily newspapers contain information on stock prices, economic figures, quarterly business reports on earnings and revenues, and much more. These data offer observed values of given quantities. The basic data types can be qualitative, ordinal, or quantitative.

In this entry, we will present the first essentials of data description. We describe all data types and levels. We explain and illustrate why one has to be careful about the permissible computations concerning each data level.¹

We will restrict ourselves to *univariate data*, that is, data of only one dimension. For example, if you follow the daily returns of one particular stock, you obtain a one-dimensional series of observations. If you had observed two stocks, then you would have obtained a two-dimensional series of data, and so on. Moreover, the notion of frequency distributions, empirical frequency distributions, and cumulative frequency distributions is introduced. The goal of this entry is to provide the first methods

necessary to begin data analysis. After reading this entry you will learn how to formalize the first impression you obtain from the data in order to retrieve the most basic structure inherent in the data. That is essential for any subsequent tasks you may undertake with the data. Above all, though, you will have to be fully aware of what you want to learn from the data. That step is maybe the most important task before getting started in investigating the data. For example, you may just want to know what the minimum return has been of your favorite stock during the last year before you decide to purchase. Or you are interested in all returns from last year to learn how this stock typically performs, that is, which returns occur more often than others,

and how often. In the latter case, you definitely have to be more involved to obtain the necessary information than in the first case.

DATA TYPES

Data are gathered by several methods. In the financial industry, we have market data based on regular trades recorded by the exchanges. These data are directly observable. Aside from the regular trading process, there is so-called over-the-counter (OTC) business whose data are less accessible. Annual reports and quarterly reports, on the other hand, are published by companies themselves in print or electronically. These data are available also in the business and finance sections of most major business oriented print media and the Internet. The fields of marketing and the social sciences know additional forms of data collection methods. There are telephone surveys, mail questionnaires, and even experiments.

If one does research on certain financial quantities of interest, one might find the data available from either free or commercial databases. Hence, one must be concerned with the quality of the data. Unfortunately, very often databases of unrestricted access such as those available on the Internet may be of limited credibility. In contrast, there are many commercial purveyors of financial data who are generally acknowledged as providing accurate data. But, as always, quality may have its price.

Information Contained in the Data

Once the data are gathered, it is the objective of descriptive statistics to visually and computationally convert the amount of information given into quantities revealing the essentials in which we are interested. Commonly in this context, visual support is added since very often that allows for a much easier grasp of the information.

The field of descriptive statistics discerns different types of data. Very generally, there are two types: qualitative and quantitative data.

If certain attributes of an item can only be assigned to categories, these data are referred to as qualitative. For example, stocks listed on the New York Stock Exchange (NYSE) can be categorized as belonging to a specific industry sector such as “banking,” “energy,” “media and telecommunications,” and so on. That way, we assign the item stock as its attribute sector one or possibly more values from the set containing banking, energy, media and telecommunications, and so on. (Instead of attribute, we will most of the time use the term “variable.”) Another example would be the credit ratings assigned to debt obligations by commercial rating companies such as Standard & Poor’s, Moody’s, and Fitch Ratings. Except for retrieving the value of an attribute, nothing more can be done with *qualitative data*. One may use a numerical code to indicate the different sectors (e.g., 1 = banking, 2 = energy, and so on). However, we are not allowed to perform any computation with these figures since they are simply proxies of the underlying attribute sector.

However, if an item is assigned a quantitative variable, the value of this variable is numerical. Generally, all real numbers are eligible. Depending on the case, however, one will use discrete values only, such as integers. Stock prices or dividends, for example, are *quantitative data* drawing from—up to some digits—positive real numbers. Quantitative data have the feature that one can perform transformations and computations with them. One can easily think of the average price of all companies comprising some index on a certain day, while it would make absolutely no sense to do the same with qualitative data.

Data Levels and Scale

In descriptive statistics, we group data according to measurement levels. The measurement level gives an indication as to the sophistication of the analysis techniques that one can

apply to the data collected. Typically, a hierarchy with five levels of measurement—nominal, ordinal, interval, ratio, and absolute—is used to group data. The latter three form the set of quantitative data. If the data are of a certain measurement level, they are said to be scaled accordingly. That is, the data are referred to as nominally scaled, and so on.

Nominally scaled data are on the bottom of the hierarchy. Despite the low level of sophistication, this type of data are commonly used. An example is the attribute sector of stocks. We already learned that, even though we can assign numbers as proxies to nominal values, these numbers have no numerical meaning whatsoever. We might just as well assign letters to the individual nominal values, for example, “B = banking,” “E = energy,” and so on.

Ordinally scaled data are one step higher in the hierarchy. We also refer to this type as “rank data,” since we can already perform a ranking within the set of values. We can make use of a relationship among the different values by treating them as quality grades. For example, we can divide the stocks listed in a particular stock index according to their market capitalization into five groups of equal size. Let “A” denote the top 20% of the stocks. Also, let “B” denote the next 20% below, and so on, until we obtain the five groups: A, B, C, D, and E. After ordinal scaling, we can make statements such as “Group A is better than group C.” Hence, we have a natural ranking or order among the values. However, we cannot quantify the difference between them. Also, the credit rating of debt obligations is ordinarily scaled.

Until now, we can summarize that while we can test the relationship between nominal data for equality only, we can additionally determine a greater or less than relationship between *ordinal data*.

Data on an *interval scale* are given if they can be reasonably transformed by a linear equation. Suppose we are given values x . It is now feasible to express a new variable y by the relationship $y = a^* x + b$, where the x 's are our original

data. If x has a meaning, then so does y . It is obvious that data have to possess a numerical meaning and therefore be quantitative in order to be measured on an interval scale. For example, consider the temperature F given in degrees Fahrenheit. Then, the corresponding temperature in degrees Celsius, C , will result from the equation $C = (F - 32)/ 1.8$. Equivalently, if one is familiar with physics, the same temperature measured in degrees Kelvin, K , will result from $K = C + 273.15$. So, say it is 55° Fahrenheit for Americans, the same temperature will mean approximately 13° Celsius for Europeans, and they will not feel any cooler. Generally, interval data allow for the calculation of differences. For example, 70° – 60° Fahrenheit = 10° Fahrenheit may reasonably express the difference in temperature between Los Angeles and San Francisco. But be careful—the difference in temperature measured in Celsius between the two cities is not the same. How much is it?

Data measured on a *ratio scale* share all the properties of interval data. In addition, ratio data have a fixed or true zero point. This is not the case with interval data. Their intercept, b , can be arbitrarily changed through transformation. Since the zero point of ratio data is invariable, one can only transform the slope, a . So, for example, $y = a^* x$ is always a multiple of x . In other words, there is a relationship between y and x given by the ratio a , hence the name used to describe this type of data. One would not have this feature if one would permit some b different from zero in the transformation. Consider, for example, the stock price, E , of some European stock given in euro units. The same price in U.S. dollars, D , would be D equals E times the exchange rate between euros and U.S. dollars. But if the company's price after bankruptcy went to zero, the price in either currency would be zero, even at different rates determined by the ratio of U.S. dollar per euro. This is a result of the invariant zero point.

Absolute data are given by quantitative data measured on a scale even stricter than for

ratio data. Here, along with the zero point, the units are invariant as well. Data measured on an absolute scale occur when transformation would be mathematically feasible but lacks any interpretational implication. A common example is provided by counting numbers. Anybody would agree on the number of stocks listed in a certain stock index. There is no ambiguity as to the zero point and the count increments. If one stock is added to the index, it is immediately clear that the difference to the content of the old index is exactly one unit of stock, assuming that no stock is deleted. This absolute scale is the most intuitive and needs no further discussion.

Cross-Sectional and Time Series Data

There is another way of classifying data. Imagine collecting data from one and the same quantity of interest or variable. A variable is some quantity that can assume values from a value set. For example, the variable “stock price” can technically assume any nonnegative real number of currency but only one value at a time. Each day, it assumes a certain value, which is the day’s stock price. As another example, a variable could be the dividend payments from a specific company over some period of time. In the case of dividends, the observations are made each quarter. The accumulated data then form what is called *time series data*. In contrast, one could pick a particular time period of interest such as the first quarter of the current year and observe the dividend payments of all companies listed in the Standard & Poor’s 500 index. By doing so, one would obtain *cross-sectional data* of the universe of stocks in the S&P 500 index at that particular time.

Summarizing, time series data are data related to a variable successively observed at a sequence of points in time. Cross-sectional data are values of a particular variable across some universe of items observed at a unique point in time. This is visualized in Figure 1.

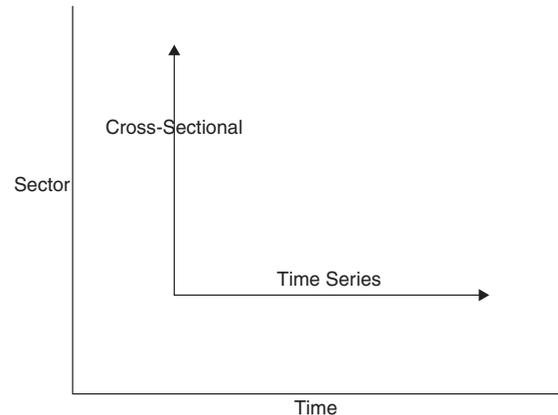

Figure 1 Relationship between Cross-Sectional and Time Series Data

FREQUENCY DISTRIBUTIONS

Sorting and Counting Data

One of the most important aspects when dealing with data is that they are effectively organized and transformed in order to convey the essential information contained in them. This processing of the original data helps to display the inherent meaning in a way that is more accessible for intuition. But before advancing to the graphical presentation of the data, we will first describe the methods of structuring data.

Suppose that we are interested in a particular variable that can assume a set of either finite or infinitely many values. These values may be qualitative or quantitative by nature. In either case, the initial step when obtaining a data sample for some variable is to sort the values of each observation and then to determine the frequency distribution of the dataset. This is done simply by counting the number of observations for each possible value of the variable. Alternatively, if the variable can assume values on all or part of the real line, the frequency can be determined by counting the number of observations that fall into nonoverlapping intervals partitioning the real line.

In our illustration, we will begin with qualitative data first and then move on to the

quantitative aspects in the sequel. For example, suppose we want to analyze the frequency of the industry subsectors of the components listed in the Dow Jones Industrial Average (DJIA), an index comprised of 30 U.S. stocks. Table 1 displays the 30 companies in the index along with their respective industry sectors as of December 12, 2006. By counting the observed number of each possible Industry Clas-

Tobacco	1

sification Benchmark (ICB) subsector, we obtain Table 2, which shows the frequency distribution of the variable subsector. Note in the table that many subsector values appear only once. Hence, this might suggest employing a coarser set for the ICB subsector values in order to reduce the amount of information in the data to a necessary minimum.

Now suppose you would like to compare this to the Dow Jones Global Titans 50 Index (DJGTI). This index includes the 50 largest-capitalization and best-known blue-chip companies listed on the NYSE. The companies contained in this index are listed in Table 3 along with their respective ICB subsectors. The next step would also be to sort the data according to their values and count each hit of a value, finally listing the respective count numbers for each value. A problem arises now, however, when you want to directly compare the numbers with those obtained for the DJIA because the number of stocks contained in each index is not the same. Hence, we cannot compare the respective

absolute frequencies. Instead, we have to resort to something that creates comparability of the two datasets. This is done by expressing the number of observations of a particular value as the proportion of the total number of observations in a specific dataset. That means we have to compute the relative frequency. See Table 4.

Formal Presentation of Frequency

For a better formal presentation, we denote the (absolute) frequency by a and, in particular, by a_i for the i th value of the variable. Formally, the relative frequency f_i of the i th value is, then, defined by

$$f_i = \frac{a_i}{n}$$

where n is the total number of observations. With k being the number of the different values, the following holds:

$$n = \sum_{i=1}^k f_i$$

In our illustration, let $n_1 = 30$ be the number of total observations in the DJIA and $n_2 = 50$ the total number of observations in the DJGTI. Table 4 shows the relative frequencies for all possible values. Notice that each index has some values that were observed with zero frequency, which still have to be listed for comparison. When we look at the DJIA, we find out that the sectors Diversified Industrials and Pharmaceuticals each account for 10% of all sectors and therefore are the sectors with the highest frequencies. Comparing these two sectors to the DJGTI, we find out that Pharmaceuticals play as important a role as a sector with an 18% share, while Diversified Industrials are of minor importance. In this index, Banks are a very important sector with 18% also. A comparison of this sort can now be carried through for all subsectors thanks to the relative frequencies.

Naturally, frequency (absolute and relative) distributions can be computed for all types of data since they do not require that the data have a numerical value.

EMPIRICAL CUMULATIVE FREQUENCY DISTRIBUTION

Accumulating Frequencies

In addition to the frequency distribution, there is another quantity of interest for comparing data that is closely related to the absolute or relative frequency distribution. Suppose that one is interested in the percentage of all large-capitalization stocks in the DJIA with closing prices of at most US \$50 on a specific day. One can sort the observed closing prices by their numerical values in ascending order to obtain something like the array shown in Table 5 for market prices as of December 15, 2006. Note that

Table 5 DJIA Stocks by Share Price in Ascending Order as of December 15, 2006

since each value occurs once only, we have to assign each value an absolute frequency of 1 or a relative frequency of $1/30$, respectively, since there are 30 component stocks in the DJIA. We start with the lowest entry (\$20.77) and advance up to the largest value still less than \$50, which is \$49 (Coca-Cola). Each time we observe less than or equal to \$50, we add $1/30$, accounting for the frequency of each company to obtain an accumulated frequency of $18/30$ representing the total share of closing prices below \$50. This accumulated frequency is called the “empirical cumulative frequency” at the value \$50. If one computes this for all values, one obtains the empirical cumulative frequency distribution. The term “empirical” is used because the distribution is computed from observed data.

Formal Presentation of Cumulative Frequency Distributions

Formally, the empirical cumulative frequency distribution F_{emp} is defined as

$$F_{emp}(x) = \sum_{i=1}^k a_i$$

where k is the index of the largest value observed that is still less than x . In our example, k is 18. When we use relative frequencies, we obtain the empirical relative cumulative frequency distribution defined analogously to the empirical cumulative frequency distribution, this time using relative frequencies. Hence, we have

$$F_{emp}^f(x) = \sum_{i=1}^k f_i$$

In our example, $F_{emp}^f(50) = 18/30 = 0.6 = 60\%$.

Note that the empirical cumulative frequency distribution can be evaluated at any real x even though x need not be an observation. For any value x between two successive observations $x_{(i)}$ and $x_{(i+1)}$, the empirical cumulative frequency distribution as well as the empirical cumulative relative frequency distribution remain at their respective levels at $x_{(i)}$; that is, they are of constant level $F_{emp}(x_{(i)})$ and $F_{emp}^f(x_{(i)})$, respectively. For example, consider the empirical relative cumulative frequency distribution for the data shown in Table 5. We can extend the distribution to a function that determines the value of the distribution at each possible value of the share price. The function is given in Table 6. Notice that if no value is observed more than once, then the empirical relative cumulative frequency distribution jumps by $1/N$ at each observed value. In our illustration, the jump size is $1/30$.

In Figure 2 the empirical relative cumulative frequency distribution is shown as a graph. Note that the values of the function are constant on the extended line between two successive observations, indicated by the solid point to the

0.83	72.03	$\leq x <$	78.73
0.87	78.73	$\leq x <$	78.77
0.90	78.77	$\leq x <$	84.97
0.93	84.97	$\leq x <$	89.93
0.97	89.93	$\leq x <$	95.36
1.00	95.36	$\leq x$	

left of each horizontal line. At each observation, the vertical distance between the horizontal line extending to the right from the preceding observation and the value of the function is exactly the increment $1/30$.

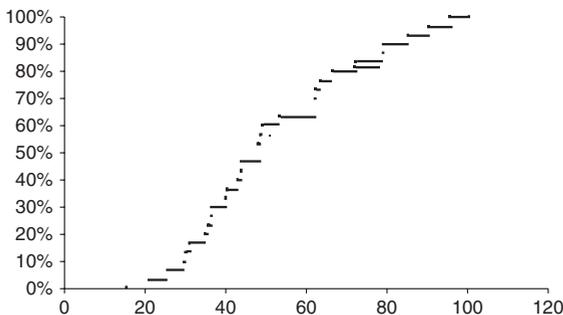

Figure 2 Empirical Relative Cumulative Frequency Distribution of DJIA Stocks from Table 5

The computation of either form of empirical cumulative distribution function is obviously not intuitive for categorical data unless we assign some meaningless numerical proxy to each value such as “Sector A” = 1, “Sector B” = 2, and so on.

DATA CLASSES

Reasons for Classifying

When quantitative variables are such that the set of values—whether observed or theoretically possible—includes intervals or the entire real numbers, then the variable is continuous. This is in contrast to discrete variables, which assume values only from a limited or countable set. Variables on a nominal scale cannot be considered in this context. And because of the difficulties with interpreting the results, we will not attempt to explain the issue of classes for rank data either.

When one counts the frequency of observed values of a continuous variable, one notices that hardly any value occurs more than once. (Naturally, the precision given by the number of digits rounded may result in higher occurrences of certain values.) Theoretically, with 100% chance, all observations will yield different values. Thus, the method of counting the frequency of each value is not feasible. Instead, the continuous set of values is divided into mutually exclusive intervals. Then, for each such interval, the number of values falling within that interval can be counted again. In other words, one groups the data into classes for which the frequencies can be computed. Classes should be such that their respective lower and upper bounds are real numbers. Also, whether the class bounds are elements of the classes or not must be specified. The class bounds of a class must be bounds of the respective adjacent classes as well, such that the classes seamlessly cover the entire data. The width should be the same for all classes. However, if there are areas where the data are very intensely dense in contrast to areas of lesser density, then the

class width can vary according to significant changes in value density. In certain cases, most of the data are relatively evenly scattered within some range, while there are extreme values that are located in isolated areas on either end of the data array. Then, it is sometimes advisable to specify no lower bound to the lowest class and no upper bound to the uppermost class. Classes of this sort are called “open classes.” Moreover, one should consider the precision to which the data are given. If values are rounded to the first decimal but there is the chance that the exact value might vary within half a decimal about the value given, class bounds have to consider this lack of certainty by admitting plus half a decimal on either end of the class.

Formal Procedure of Classifying

Formally, there are four criteria that the classes need to meet:

Criterion 1: *Mutual Exclusiveness*: Each value can be placed in only one class.

Criterion 2: *Completeness*: The set of classes needs to cover all values.

Criterion 3: *Equidistance*: If possible, form classes of equal width.

Criterion 4: *Nonemptiness*: If possible, avoid forming empty classes.

It is intuitive that the number of classes should increase with an increasing range of values and increasing number of data. Though there are no stringent rules, two rules of thumb are given here with respect to the advised number of classes (first rule) and the best class width (second rule). The first, the so-called Sturge’s rule, states that for a given set of continuous data of size n , one should use the nearest integer figure to

$$1 + \log_2 n = 1 + 3.222 \log_{10} n.$$

Here, $\log_a n$ denotes the logarithm of n to the base a , with a being either 2 or 10.

The second guideline is the so-called *Freedman-Diaconis rule* for the appropriate class width or bin size. Before turning to the second

rule of thumb in more detail, we have to introduce the notion of the *inner quartile range (IQR)*. This quantity measures the distance between the value where F_{emp}^f is closest to 0.25 (that is, the so-called 0.25-quantile), and the value where F_{emp}^f is closest to 0.75 (that is, the so-called 0.75-quantile). (The term “percentile” is used interchangeably with “quantile.”) So the IQR range states how remote the lowest 25% of the observations are from the highest 25%.² As a consequence, the IQR comprises the central 50% of a data sample. A little more attention will be given to the determination of the above-mentioned quantiles when we discuss sample moments and quantiles, since formally there might arise some ambiguity when computing them. (Note that the IQR cannot be computed for nominal or categorical data in a natural way.)

Now we can return to the Freedman-Diaconis rule. It states that a good class width is given by the nearest integer to

$$2 \times IQR \times N^{-1/3}$$

where N is the number of observations in the dataset. Note that there is an inverse relationship between the class width and the number of classes for each set of data. That is, given that the partitioning of the values into classes covers all observations, the number of classes n has to be equal to the difference between largest and smallest value divided by the class width, if classes are all of equal size w . Mathematically, that means

$$n = (x_{\max} - x_{\min})/w$$

where x_{\max} denotes the largest value and x_{\min} denotes the smallest value considered, respectively.

One should not be intimidated by all these rules. Generally, by mere ordering of the data in an array, intuition produces quite a good feeling of what the classes should look like. Some thought can be given to the timing of the formation of the classes. That is, when classes are formed prior to the data-gathering process, one does not have to store the specific values but

rather count only the number of hits within each class.

Example of Classing Procedures

Let's illustrate these rules. Table 7 gives the 12-month returns (in percent) of the 235 Franklin Templeton Investments Funds on January 11, 2007. With this many data, it becomes obvious that it cannot be helpful to anyone to know the relative performance for the 235 funds. To obtain an overall impression of the distribution of the data without getting lost in detail, one has to aggregate the information given by classifying the data.

For the sake of a better overview, the ordered array is given in Table 8. A quick glance at the data sorted in ascending order gives us the lowest (minimum) and largest (maximum) return, respectively. Here, we have $x_{\min} = -18.3\%$ and $x_{\max} = 41.3\%$, respectively, yielding a range of 59.6% to cover.

We first classify the data according to Sturge's rule. For the number of classes, n , we obtain the nearest integer to $1 + \log_2 235 = 8.877$, which is 9. The class width is then determined by the range divided by the number of classes, $59.6\%/9$, yielding a width of roughly 6.62%. This is not a nice number to deal with, so we may choose 7% instead without deviating noticeably from the exact numbers given by Sturge's rule. We now cover a range of $9 \times 7\% = 63\%$, which is slightly larger than the original range of the data.

Selecting a value for the lower class bound of the lowest class slightly below our minimum, say -20.0% , and an upper class bound of the highest class, say 43.0% , we spread the surplus of the range (3.4%) evenly. The resulting classes can be viewed in Table 9, where in the first row the index of the respective class is given. The second row contains the class bounds. Brackets indicate that the value belongs to the class, whereas parentheses exclude given values. So, we obtain a half-open interval for each class containing all real numbers between the lower bound and just below the upper bound, thus

excluding that value. In row three, we have the number of observations that fall into the respective classes.

We can check for the compliance with the four criteria given earlier. Because we use half-open intervals, we guarantee that Criterion 1 is fulfilled. Since the lowest class starts at -20% , and the highest class ends at 43% , Criterion 2 is satisfied. All nine classes are of width 7%, which complies with Criterion 3. Finally, the compliance with Criterion 4 can be checked easily.

Next, we apply the Freedman-Diaconis rule. With our ordered array of data, we can determine the 0.25 quartile by selecting the observation whose index is the first to exceed $0.25 \times N = .25 \times 235 = 58.75$. This yields the value of observation 59, which is 4.2%. Accordingly, the 0.75-quartile is given by the value whose index is the first to exceed $0.75 \times 235 = 176.25$. For our return data, it is x_{177} , which is 18.9%. The *IQR* is computed as

$$18.9\% - 4.2\% = 14.7\%$$

such that the bin size of the classes (or class width) is now determined according to $w = 2 \times IQR \times \frac{1}{\sqrt[3]{235}} = 4.764\%$. Taking the data range of 59.6% from the previous calculation, we obtain as the suggested number of classes $59.6\%/4.764 = 12.511$. Once again, this is not a neat-looking figure. We stick with the initial class width of $w = 4.764\%$ as closely as possible by selecting the next integer, say 5%. And, without any loss, we extend the range artificially to 60%. So, we obtain for the number of classes $60\%/5 = 12$, which is close to our original real number, 12.511, computed according to the Freedman-Diaconis rule but much nicer to handle. We again spread the range surplus of 0.4% ($60\% - 59.6\%$) evenly across either end of the range such that we begin our lowest class at -18.5% and end our highest class at 41.5% . The classes are given in Table 10. The first row of the table indicates the index of the respective class, while the second row gives the class bounds. The number of observations that fall into each class is shown in the last row. (One can easily

check that the four requirements for the classes are met again.)

Let us next compare Tables 9 and 10. We observe a finer distribution when the Freedman-Diaconis rule is employed because this rule generates more classes for the same data. However, it is generally difficult to judge which rule provides us with the better information because, as is seen, the two rules set up completely different classes. But the choice of class bounds is essential. By just slightly shifting the

bounds between two adjacent classes, many observations may fall from one class into the other due to this alteration. As a result, this might produce a totally different picture about the data distribution. So, we have to be very careful when we interpret the two different results.

For example, class 7, that is, [22,29) in Table 9 contains 16 observations. Classes 9 and 10 of Table 10 cover approximately the same range, [21.5,31.5). Together they account for 20 observations. We could now easily present two

Table 9 Classes for the 235 Fund Returns According to Sturge's Rule

scenarios that would provide rather different conceptions about the frequency. In scenario one, suppose one assumes that two observations are between 21.5 and 22.0. Then, there would have to be 16 observations between 22.0 and 26.5 to add up to 18 observations in class 9 of Table 10. This, in return, would mean that the 16 observations of class 7 from Table 9 would all have to lie between 22.0 and 26.5 as well. Then, the two observations from class 10 of Table 10 must lie beyond 29.0. The other scenario could assume that we have four observations between 21.5 and 22.0. Then, for similar reasons as before, we would have 14 observations between 22.0 and 26.5. The two observations from class 10 of Table 10 would now have to be between 26.5 and 29.0, so that the total of 16 observations in class 7 of Table 9 is met. See how easily slightly different classes can lead to ambiguous interpretation? Looking at all classes at once, many of these puzzles can be solved. However, some uncertainty remains. As can be seen, the choice of the number of classes and thus the class bounds can have a significant impact on the information that the data conveys when condensed into classes.

CUMULATIVE FREQUENCY DISTRIBUTIONS

In contrast to the empirical cumulative frequency distributions, in this section we will introduce functions that convey basically the same information, that is, the *frequency distribu-*

tion, but rely on a few more assumptions. These cumulative frequency distributions introduced here, however, should not be confused with the theoretical definitions given in probability theory even though the notion is akin to both.

The absolute cumulative frequency at each class bound states how many observations have been counted up to this particular class bound. However, we do not exactly know how the data are distributed within the classes. When relative frequencies are used, though, the cumulative relative frequency distribution states the overall proportion of all values up to a certain lower or upper bound of some class.

So far, things are not much different from the definition of the empirical cumulative frequency distribution and *empirical cumulative relative frequency distribution*. At each bound, the empirical cumulative frequency distribution and cumulative frequency coincide. However, an additional assumption is made regarding the distribution of the values between bounds of each class when computing the cumulative frequency distribution. The data are thought of as being continuously distributed and equally spread between the particular bounds. (This type of assumed behavior is defined as a "uniform distribution of data.") Hence, both forms (absolute and relative) of the cumulative frequency distributions increase in a linear fashion between the two class bounds. So, for both forms of cumulative distribution functions, one can compute the accumulated frequencies at values inside of classes.

Table 10 Classes for the 235 Fund Returns According to the Freedman-Diaconis Rule

$[a_i, b_i)$	[-18.5; -13.5)	[-13.5; -8.5)	[-8.5; -3.5)	[-3.5; 1.5)	[1.5; 6.5)	[6.5; 11.5)	[11.5; 16.5)	[16.5; 21.5)	[21.5; 26.5)	[26.5; 31.5)	[31.5; 36.5)	[36.5; 41.5)
a_i	2	4	5	18	42	35	57	36	18	2	9	7

For a more thorough summary of this, let's use a more formal presentation. Let I denote the set of all class index i with i being some integer value between 1 and $n_I = |I|$ (that is, the number of classes). Moreover, let a_j and f_j denote the (absolute) frequency and relative frequency of some class j , respectively. The cumulative frequency distribution at some upper bound, x_u^i , of a given class i is computed as

$$F(x_u^i) = \sum_{j:x_j^l \leq x_u^i} a_j = \sum_{j:x_j^l \leq x_u^i} a_j + a_i \quad (1)$$

In words, this means that we sum up the frequencies of all classes whose upper bound is less than x_u^i plus the frequency of class i itself. The corresponding cumulative relative frequency distribution at the same value is then

$$F^f(x_u^i) = \sum_{j:x_j^l \leq x_u^i} f_j = \sum_{j:x_j^l \leq x_u^i} f_j + f_i \quad (2)$$

This describes the same procedure as in equation (1) using relative frequencies instead of frequencies. For any value x in between the boundaries of, say, class i , x_l^i and x_u^i , the cumulative relative frequency distribution is defined by

$$F^f(x) = F^f(x_l^i) + \frac{x - x_l^i}{x_u^i - x_l^i} f_i \quad (3)$$

In words, this means that we compute the cumulative relative frequency distribution at value x as the sum of two things. First, we take the cumulative relative frequency distribution at the lower bound of class i . Second, we add that share of the relative frequency of class i that is determined by the part of the whole interval of class i that is covered by x .

Figure 3 might appeal more to intuition. At the bounds of class i , we have values of the cumulative relative frequency given by $F^f(x_l^i)$ and $F^f(x_u^i)$ respectively. We assume that the cumulative relative frequency increases linearly along the line connecting $F^f(x_l^i)$ and $F^f(x_u^i)$. Then, at any value x^* inside of class i , we find the corresponding value $F^f(x^*)$ by the intersection of the dashed line and the vertical axis as shown. The dashed line is obtained by ex-

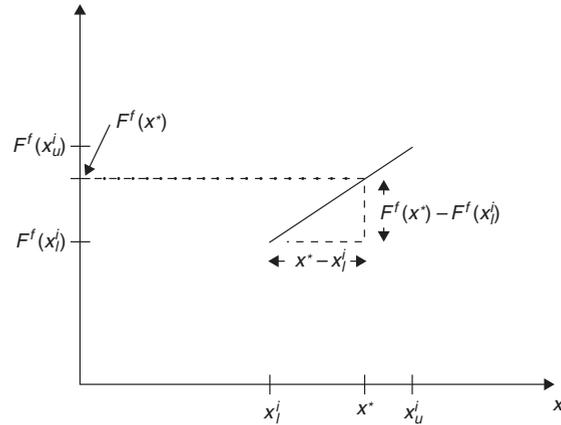

Figure 3 Determination of Frequency Distribution within Class Bounds

tending a horizontal line through the intersection of the vertical line through x^* and the line connecting $F^f(x_l^i)$ and $F^f(x_u^i)$ with slope $F^f(x^*) - F^f(x_l^i)/x^* - x_l^i$.

KEY POINTS

- The field of descriptive statistics discerns different types of data. Very generally, there are two types: qualitative and quantitative data. If certain attributes of an item can only be assigned to categories, these data are referred to as qualitative. However, if an item is assigned a quantitative variable, the value of this variable is numerical. Generally, all real numbers are eligible.
- In descriptive statistics, data are grouped according to measurement levels. The measurement level gives an indication as to the sophistication of the analysis techniques that can be applied to the data collected. Typically, a hierarchy with five levels of measurement—nominal, ordinal, interval, ratio, and absolute data—are used to group data. The latter three form the set of quantitative data. If the data are of a certain measurement level, they are said to be scaled accordingly. That is, the data are referred to as nominally scaled, and so on.
- Another way of classifying data is in terms of cross-sectional and time series data.

Cross-sectional data are values of a particular variable across some universe of items observed at a unique point in time. Time series data are data related to a variable successively observed at a sequence of points in time.

- Frequency (absolute and relative) distributions can be computed for all types of data since they do not require that the data have a numerical value. The cumulative frequency distribution is another quantity of interest for comparing data that is closely related to the absolute or relative frequency distribution.
- Four criteria that data classes need to satisfy are (1) each value can be placed in only one class (mutual exclusiveness), (2) the set of classes needs to cover all values (completeness), (3) if possible, form classes of equal width (equidistance), and

(4) if possible, avoid forming empty classes (nonemptiness).

NOTES

1. For a more detailed discussion, see Rachev et al. (2010).
2. The 0.75-quantile divides the data into the lowest 75% and the highest 25%.

Professor of Finance, EDHEC Business School

Abstract: A stochastic process is a time-dependent random variable. Stochastic processes such as Brownian motion and Ito processes develop in continuous time. This means that time is a real variable that can assume any real value. In many financial modeling applications, however, it is convenient to constrain time to assume only discrete values. A time series is a discrete-time stochastic process; that is, it is a collection of random variables X_t indexed with the integers $\dots, -n, \dots, -2, -1, 0, 1, 2, \dots, n, \dots$

In this entry, we introduce models of *discrete-time stochastic processes* (that is, time series). In financial modeling, both continuous-time and discrete-time models are used. In many instances, continuous-time models allow simpler and more concise expressions as well as more general conclusions, though at the expense of conceptual complication. For instance, in the limit of continuous time, apparently simple processes such as white noise cannot be meaningfully defined. The mathematics of asset management tends to prefer discrete-time processes, while the mathematics of derivatives tends to prefer continuous-time processes.

The first issue to address in financial econometrics is the spacing of discrete points of time. An obvious choice is regular, constant spacing. In this case, the time points are placed at multiples of a single time interval: $t = i \Delta t$. For

instance, one might consider the closing prices at the end of each day. The use of fixed spacing is appropriate in many applications. Spacing of time points might also be irregular but deterministic. For instance, weekends introduce irregular spacing in a sequence of daily closing prices. These questions can be easily handled within the context of discrete-time series.

In this entry, we discuss only time series at discrete and fixed intervals of time, introducing concepts, representations, and models of time series.¹

CONCEPTS OF TIME SERIES

A time series is a collection of random variables X_t indexed with a discrete time index $t = \dots, -2, -1, 0, 1, 2, \dots$. The variables X_t are defined over a

probability space $(\Omega, P, \mathfrak{J})$, where Ω is the set of states, P is a probability measure, and \mathfrak{J} is the σ -algebra of events, equipped with a discrete *filtration* $\{\mathfrak{J}_t\}$ that determines the propagation of information (see the Appendix). A realization of a time series is a countable sequence of real numbers, one for each time point.

The variables X_t are characterized by *finite-dimensional distributions* as well as by conditional distributions, $F_s(x_s/\mathfrak{J}_t)$, $s > t$. The latter are the distributions of the variable x at time s given the σ -algebra $\{\mathfrak{J}_t\}$ at time t . Note that conditioning is always conditioning with respect to a σ -algebra though we will not always strictly use this notation and will condition with respect to the value of variables, for instance:

$$F_s(x_s/x_t), \quad s > t$$

If the series starts from a given point, initial conditions must be fixed. Initial conditions might be a set of fixed values or a set of random variables. If the initial conditions are not fixed values but random variables, one has to consider the correlation between the initial values and the random shocks of the series. A usual assumption is that the initial conditions and the random shocks of the series are statistically independent.

How do we describe a time series? One way to describe a time series is to determine the mathematical form of the conditional distribution. This description is called an *autopredictive model* because the model predicts future values of the series from past values. However, we can also describe a time series as a function of another time series. This is called an explanatory model as one variable is explained by another. The simplest example is a regression model where a variable is proportional to another exogenously given variable plus a constant term. Time series can also be described as random fluctuations or adjustments around a deterministic path. These models are called *adjustment models*. Explanatory, autopredictive, and adjustment models can be mixed in a single model. The *data generation process* (DGP) of a series is a mathemat-

ical process that computes the future values of the variables given all information known at time t .

An important concept is that of a *stationary time series*. A series is stationary in the “strict sense” if all finite dimensional distributions are invariant with respect to a time shift. A series is stationary in a “weak sense” if only the moments up to a given order are invariant with respect to a time shift. In this entry, time series will be considered (weakly) stationary if the first two moments are time-independent. Note that a stationary series cannot have a starting point but must extend over the entire infinite time axis. Note also that a series can be strictly stationary (i.e., have all distributions time-independent, but the moments might not exist). Thus a strictly stationary series is not necessarily weakly stationary.

A time series can be univariate or multivariate. A *multivariate time series* is a time-dependent random vector. The principles of modeling remain the same but the problem of estimation might become very difficult given the large numbers of parameters to be estimated.

Models of time series are essential building blocks for financial forecasting and, therefore, for financial decision-making. In particular asset allocation and portfolio optimization, when performed quantitatively, are based on some model of financial prices and returns. This entry lays down the basic financial econometric theory for financial forecasting. We will introduce a number of specific models of time series and of multivariate time series, presenting the basic facts about the theory of these processes. We will consider primarily models of financial assets, though most theoretical considerations apply to macroeconomic variables as well. These models include:

- **Correlated random walks.** The simplest model of multiple financial assets is that of *correlated random walks*. This model is only a rough approximation of equity price processes and presents serious problems of

estimation in the case of a large number of processes.

- **Factor models.** *Factor models* address the problem of estimation in the case of a large number of processes. In a factor model there are correlations only among factors and between each factor and each time series. Factors might be exogenous or endogenously modeled.
- **Cointegrated models.** In a *cointegrated model* there are portfolios that are described by autocorrelated, stationary processes. All processes are linear combinations of common trends that are represented by the factors.

The above models are all linear. However, nonlinearities are at work in financial time series. One way to model nonlinearities is to break down models into two components, the first being a linear autoregressive model of the parameters, the second a regressive or autoregressive model of empirical quantities whose parameters are driven by the first. This is the case with most of today's nonlinear models (e.g., ARCH/GARCH models), Hamilton models, and Markov switching models.

There is a coherent modeling landscape, from correlated random walks and factor models to the modeling of factors, and, finally, the modeling of nonlinearities by making the model parameters vary. Before describing models in detail, however, let's present some key empirical facts about financial time series.

STYLIZED FACTS OF FINANCIAL TIME SERIES

Most sciences are stratified in the sense that theories are organized on different levels. The empirical evidence that supports a theory is generally formulated in a lower level theory. In physics, for instance, quantum mechanics cannot be formulated as a stand-alone theory but needs classical physics to give meaning to measurement. Economics is no exception. A basic level of knowledge in economics is represented

by the so-called stylized facts. Stylized facts are statistical findings of a general nature on financial and economic time series; they cannot be considered raw data insofar as they are formulated as statistical hypotheses. On the other hand, they are not full-fledged theories.

Among the most important stylized facts from the point of view of finance theory, we can mention the following:

- Returns of individual stocks exhibit nearly zero autocorrelation at every lag.
- Returns of some equity portfolios exhibit significant autocorrelation.
- The volatility of returns exhibits hyperbolic decay with significant autocorrelation.
- The distribution of stock returns is not normal. The exact shape is difficult to ascertain but power law decay cannot be rejected.
- There are large stock price drops (that is, market crashes) that seem to be outliers with respect to both normal distributions and power law distributions.
- Stock return time series exhibit significant cross-correlation.

These findings are, in a sense, model-dependent. For instance, the distribution of returns, a subject that has received a lot of attention, can be fitted by different distributions. There is no firm evidence on the exact value of the power exponent, with alternative proposals based on variable exponents. The autocorrelation is model-dependent while the exponential decay of return autocorrelation can be interpreted only as absence of linear dependence.

It is fair to say that these stylized facts set the stage for financial modeling but leave ample room for model selection. Financial time series seem to be nearly random processes that exhibit significant cross correlations and, in some instances, cross autocorrelations. The global structure of auto and cross correlations, if it exists at all, must be fairly complex and there is no immediate evidence that financial time series admit a simple DGP.

One more important feature of financial time series is the presence of trends. *Prima facie* trends of economic and financial variables are exponential trends. Trends are not quantities that can be independently measured. Trends characterize an entire stochastic model. Therefore there is no way to arrive at an assessment of trends independent from the model. Exponential trends are a reasonable first approximation.

Given the finite nature of world resources, exponential trends are not sustainable in the long run. However, they might still be a good approximation over limited time horizons. An additional insight into financial time series comes from the consideration of investors' behavior. If investors are risk averse, as required by the theory of investment, then price processes must exhibit a trade-off between risk and returns. The combination of this insight with the assumption of exponential trends yields market models with possibly diverging exponential trends for prices and market capitalization.

Again, diverging exponential trends are difficult to justify in the long run as they would imply that after a while only one entity would dominate the entire market. Some form of reversion to the mean or more disruptive phenomena that prevent time series to diverge exponentially must be at work.

In the following sections we will proceed to describe the theory and the estimation procedures of a number of market models that have been proposed. We will present the multivariate random walk model, introduce cointegration and autoregressive models.

INFINITE MOVING-AVERAGE AND AUTOREGRESSIVE REPRESENTATION OF TIME SERIES

There are several general representations (or models) of time series. This section introduces

representations based on infinite moving averages or infinite autoregressions useful from a theoretical point of view. In the practice of econometrics, however, more parsimonious models such as the ARMA models (described in the next section) are used. Representations are different for stationary and nonstationary time series. Let's start with univariate stationary time series.

Univariate Stationary Series

The most fundamental model of a univariate stationary time series is the infinite moving average of a white noise process. In fact, it can be demonstrated that under mild regularity conditions, any univariate stationary causal time series admits the following *infinite moving-average representation*:

$$x_t = \sum_{i=0}^{\infty} h_i \varepsilon_{t-i} + m$$

where the h_i are coefficients and ε_{t-i} is a one-dimensional zero-mean white-noise process. This is a *causal time series* as the present value of the series depends only on the present and past values of the noise process. A more general infinite moving-average representation would involve a summation that extends from $-\infty$ to $+\infty$. Because this representation would not make sense from an economic point of view, we will restrict ourselves only to causal time series.

A sufficient condition for the above series to be stationary is that the coefficients h_i are absolutely summable:

$$\sum_{i=0}^{\infty} |h_i| < \infty$$

The Lag Operator L

Let's now simplify the notation by introducing the lag operator L . The lag operator L is an operator that acts on an infinite series and produces another infinite series shifted one place to the

left. In other words, the lag operator replaces every element of a series with the one delayed by one time lag:

$$L(x_t) = x_{t-1}$$

The n -th power of the lag operator shifts a series by n places:

$$L^n(x_t) = x_{t-n}$$

Negative powers of the lag operator yield the forward operator F , which shifts places to the right. The lag operator can be multiplied by a scalar and different powers can be added. In this way, linear functions of different powers of the lag operator can be formed as follows:

$$A(L) = \sum_{i=1}^N a_i L^i$$

Note that if the lag operator is applied to a series that starts from a given point, initial conditions must be specified.

Within the domain of stationary series, infinite power series of the lag operator can also be formed. In fact, given a stationary series, if the coefficients h_i are absolutely summable, the series

$$\sum_{i=0}^{\infty} h_i L^i x_t$$

is well defined in the sense that it converges and defines another stationary series. It therefore makes sense to define the operator:

$$A(L) = \sum_{i=0}^{\infty} h_i L^i$$

Now consider the operator $I - \lambda L$. If $|\lambda| < 1$, this operator can be **inverted** and its inverse is given by the infinite power series,

$$(I - \lambda L)^{-1} = \sum_{i=0}^{\infty} \lambda^i L^i$$

as can be seen by multiplying $I - \lambda L$ by the power series $\sum_{i=1}^{\infty} \lambda^i L^i$:

$$(I - \lambda L) \sum_{i=1}^{\infty} \lambda^i L^i = L^0 = I$$

On the basis of this relationship, it can be demonstrated that any operator of the type

$$A(L) = \sum_{i=1}^N a_i L^i$$

can be inverted provided that the solutions of the equation

$$\sum_{i=1}^N a_i z^i = 0$$

have absolute values strictly greater than 1. The inverse operator is an infinite power series

$$A^{-1}(L) = \sum_{i=0}^{\infty} \psi_i L^i$$

Given two linear functions of the operator L , it is possible to define their product

$$A(L) = \sum_{i=1}^M a_i L^i$$

$$B(L) = \sum_{j=1}^N b_j L^j$$

$$P(L) = A(L)B(L) = \sum_{i=1}^{M+N} p_i L^i$$

$$p_i = \sum_{r=1}^i a_r b_{i-r}$$

The convolution product of two infinite series in the lag operator is defined in a similar way

$$A(L) = \sum_{i=0}^{\infty} a_i L^i$$

$$B(L) = \sum_{j=0}^{\infty} b_j L^j$$

$$C(L) = A(L) \times B(L) = \sum_{k=0}^{\infty} c_k L^k$$

$$c_k = \sum_{s=0}^k a_s b_{k-s}$$

We can define the left-inverse (right-inverse) of an infinite series as the operator $A^{-1}(L)$, such that $A^{-1}(L) \times A(L) = I$. The inverse can always be computed solving an infinite set of recursive equations provided that $a_0 \neq 0$. However, the inverse series will not necessarily be stationary. A sufficient condition for stationarity is that the coefficients of the inverse series are absolutely summable.

In general, it is possible to perform on the symbolic series

$$H(L) = \sum_{i=1}^{\infty} h_i L^i$$

the same operations that can be performed on the series

$$H(z) = \sum_{i=1}^{\infty} h_i z^i$$

with z complex variable. However operations performed on a series of lag operators neither assume nor entail convergence properties. In fact, one can think of z simply as a symbol. In particular, the inverse does not necessarily exhibit absolutely summable coefficients.

Stationary Univariate Moving Average

Using the lag operator L notation, the infinite moving-average representation can be written as follows:

$$x_t = \left(\sum_{i=0}^{\infty} h_i L^i \right) \varepsilon_t + m = H(L)\varepsilon_t + m$$

Consider now the inverse series:

$$\Pi(L) = \sum_{i=0}^{\infty} \lambda_i L^i, \quad \Pi(L)H(L) = I$$

If the coefficients λ_i are absolutely summable, we can write

$$\varepsilon_t = \Pi(L)x_t = \sum_{i=0}^{\infty} \lambda_i L^i x_{t-i}$$

and the series is said to be invertible.

Multivariate Stationary Series

The concepts of infinite moving-average representation and of invertibility defined above for univariate series carry over immediately to the multivariate case. In fact, it can be demonstrated that under mild regularity conditions, any multivariate stationary causal time series admits the following infinite moving-average representation:

$$\mathbf{x}_t = \sum_{i=0}^{\infty} \mathbf{H}_i \varepsilon_{t-i} + \mathbf{m}$$

where the \mathbf{H}_i are $n \times n$ matrices, ε_t is an n -dimensional, zero-mean, white noise process with nonsingular variance-covariance matrix Ω , and \mathbf{m} is an n -vector of constants. The coefficients \mathbf{H}_i are called Markov coefficients. This moving-average representation is called the Wold representation. Wold representation states that any series where only the past influences the present can be represented as an infinite moving average of white noise terms. Note that, as in the univariate case, the infinite moving-average representation can be written in more general terms as a sum that extends from $-\infty$ to $+\infty$. However, a series of this type is not suitable for financial modeling as it is not causal (that is, the future influences the present). Therefore we consider only moving averages that extend to past terms.

Suppose that the Markov coefficients are an absolutely summable series:

$$\sum_{i=0}^{\infty} \|\mathbf{H}_i\| < +\infty$$

where $\|\mathbf{H}\|^2$ indicates the largest eigenvalue of the matrix $\mathbf{H}\mathbf{H}'$. Under this assumption, it can be demonstrated that the series is stationary and that the (time-invariant) first two moments can be computed in the following way:

$$\text{cov}(\mathbf{x}_t, \mathbf{x}_{t-h}) = \sum_{i=0}^{\infty} \mathbf{H}_i \Omega \mathbf{H}'_{i-h}$$

$$E[\mathbf{x}_t] = \mathbf{m}$$

with the convention $\mathbf{H}_i = 0$ if $i < 0$. Note that the assumption that the Markov coefficients are an absolutely summable series is essential, otherwise the covariance matrix would not exist. For instance, if the \mathbf{H}_i were identity matrices, the variances of the series would become infinite.

As the second moments are all constants, the series is weakly stationary. We can write the time-independent autocovariance function of the series, which is an $n \times n$ matrix whose entries are a function of the lag h , as

$$\Gamma_x(h) = \sum_{i=0}^{\infty} \mathbf{H}_i \boldsymbol{\Omega} \mathbf{H}'_{i-h}$$

Under the assumption that the Markov coefficients are an absolutely summable series, we can use the lag-operator L representation and write the operator

$$\mathbf{H}(L) = \sum_{i=0}^{\infty} \mathbf{H}_i L^i$$

so that the Wold representation of a series can be written as

$$\mathbf{x}_t = \mathbf{H}(L)\boldsymbol{\varepsilon} + \mathbf{m}$$

The concept of invertibility carries over to the multivariate case. A multivariate stationary time series is said to be invertible if it can be represented in autoregressive form. Invertibility means that the white noise process can be recovered as a function of the series. In order to explain the notion of invertible processes, it is useful to introduce the generating function of the operator \mathbf{H} , defined as the following matrix power series:

$$\mathbf{H}(z) = \sum_{i=0}^{\infty} \mathbf{H}_i z^i$$

It can be demonstrated that, if $\mathbf{H}_0 = \mathbf{I}$, then $\mathbf{H}(0) = \mathbf{H}_0$ and the power series $\mathbf{H}(z)$ is invertible in the sense that it is possible to formally derive the inverse series,

$$\boldsymbol{\Pi}(z) = \sum_{i=0}^{\infty} \boldsymbol{\Pi}_i z^i$$

such that

$$\boldsymbol{\Pi}(z)\mathbf{H}(z) = (\boldsymbol{\Pi} \times \mathbf{H})(z) = \mathbf{I}$$

where the product is intended as a convolution product. If the coefficients $\boldsymbol{\Pi}_i$ are absolutely summable, as the process \mathbf{x}_t is assumed to be stationary, it can be represented in infinite autoregressive form:

$$\boldsymbol{\Pi}(L)(\mathbf{x}_t - \mathbf{m}) = \boldsymbol{\varepsilon}_t$$

In this case the process \mathbf{x}_t is said to be invertible.

From the above, it is clear that the infinite moving average representation is a more general linear representation of a stationary time than the infinite autoregressive form. A process that admits both representations is called invertible.

Nonstationary Series

Let's now look at nonstationary series. As there is no very general model of nonstationary time series valid for all nonstationary series, we have to restrict somehow the family of admissible models. Let's consider a family of *linear, moving-average, nonstationary models* of the following type:

$$\mathbf{x}_t = \sum_{i=0}^t \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i} + \mathbf{h}(t)\mathbf{z}_{-1}$$

where the \mathbf{H}_i are left unrestricted and do not necessarily form an absolutely summable series, $\mathbf{h}(t)$ is deterministic, and \mathbf{z}_{-1} is a random vector called the initial conditions, which is supposed to be uncorrelated with the white noise process. The essential differences of this linear model with respect to the Wold representation of stationary series are:

- The presence of a starting point and of initial conditions.
- The absence of restrictions on the coefficients.
- The index t , which restricts the number of summands.

The first two moments of a linear process are not constant. They can be computed in a

way similar to the infinite moving average case:

$$\text{cov}(\mathbf{x}_t \mathbf{x}_{t-h}') = \sum_{i=0}^t \mathbf{H}_i \boldsymbol{\Omega} \mathbf{H}_{i-h}' + \mathbf{h}(t) \text{var}(\mathbf{z}) \mathbf{h}'$$

$$E[\mathbf{x}_t] = \mathbf{m}_t = \mathbf{h}(t) E[\mathbf{z}]$$

Let's now see how a linear process can be expressed in autoregressive form. To simplify notation let's introduce the processes $\tilde{\boldsymbol{\varepsilon}}_t$ and $\tilde{\mathbf{x}}_t$ and the deterministic series $\tilde{\mathbf{h}}(t)$ defined as follows:

$$\tilde{\boldsymbol{\varepsilon}}_t = \begin{cases} \boldsymbol{\varepsilon}_t & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases} \quad \tilde{\mathbf{x}}_t = \begin{cases} \mathbf{x}_t & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases}$$

$$\tilde{\mathbf{h}}_t = \begin{cases} \mathbf{h}_t & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases}$$

It can be demonstrated that, due to the initial conditions, a linear process always satisfies the following autoregressive equation:

$$\boldsymbol{\Pi}(L) \tilde{\mathbf{x}}_t = \boldsymbol{\varepsilon}_t + \boldsymbol{\Pi}(L) \tilde{\mathbf{h}}_t \times (t) \mathbf{z}_{-1}$$

A random walk model

$$x_t = x_{t-1} + \varepsilon_t = \varepsilon_t + \sum_{i=1}^t \varepsilon_{t-i}$$

is an example of a linear nonstationary model.

The above linear model can also represent processes that are nearly stationary in the sense that they start from initial conditions but then converge to a stationary process. A process that converges to a stationary process is called asymptotically stationary.

We can summarize the previous discussion as follows. Under mild regularity conditions, any causal stationary series can be represented as an infinite moving average of a white noise process. If the series can also be represented in an autoregressive form, then the series is said to be invertible. Nonstationary series do not have corresponding general representations. Linear models are a broad class of nonstationary models and of asymptotically stationary models that provide the theoretical base for ARMA and state-space processes that will be discussed in the following sections.

ARMA REPRESENTATIONS

The infinite moving average or autoregressive representations of the previous section are useful theoretical tools but they cannot be applied to estimate processes. One needs a parsimonious representation with a finite number of coefficients. *Autoregressive moving average (ARMA)* models and state-space models provide such representation; though apparently conceptually different, they are statistically equivalent.

Stationary Univariate ARMA Models

Let's start with univariate stationary processes. An autoregressive process of order p – AR(p) is a process of the form:

$$x_t + a_1 x_{t-1} + \dots + a_p x_{t-p} = \varepsilon_t$$

which can be written using the lag operator as

$$A(L)x_t = (1 + a_1 L + \dots + a_p L^p)x_t$$

$$= x_t + a_1 L x_t + \dots + a_p L^p x_{t-p} = \varepsilon_t$$

Not all processes that can be written in autoregressive form are stationary. In order to study the stationarity of an autoregressive process, consider the following polynomial:

$$A(z) = 1 + a_1 z + \dots + a_p z^p$$

where z is a complex variable.

The equation

$$A(z) = 1 + a_1 z + \dots + a_p z^p = 0$$

is called the inverse characteristic equation. It can be demonstrated that if the roots of this equation, that is, its solutions, are all strictly greater than 1 in modulus (that is, the roots are outside the unit circle), then the operator $A(L)$ is invertible and admits the inverse representation:

$$x_t = A^{-1}(L)\varepsilon_t$$

$$= \sum_{i=0}^{+\infty} \lambda_i \varepsilon_{t-i}, \quad \text{with} \quad \sum_{i=0}^{+\infty} |\lambda_i| < +\infty$$

In order to avoid possible confusion, note that the solutions of the inverse characteristic equation are the reciprocal of the solution of the characteristic equation defined as

$$A(z) = z^p + a_1z^{p-1} + \dots + a_p = 0$$

Therefore an autoregressive process is invertible with an infinite moving average representation that only involves positive powers of the operator L if the solutions of the characteristic equation are all strictly smaller than 1 in absolute value. This is the condition of invertibility often stated in the literature.

Let's now consider finite moving-average representations. A process is called a moving average process of order q – $MA(q)$ if it admits the following representation:

$$\begin{aligned} x_t &= (1 + b_1L + \dots + b_pL^q)\varepsilon_t \\ &= \varepsilon_t + b_1\varepsilon_{t-1} + \dots + b_p\varepsilon_{t-q} \end{aligned}$$

In a way similar to the autoregressive case, if the roots of the equation

$$B(z) = 1 + b_1z + \dots + b_qz^q = 0$$

are all strictly greater than 1 in modulus, then the $MA(q)$ process is invertible and, therefore, admits the infinite autoregressive representation:

$$\begin{aligned} \varepsilon_t &= B^{-1}(L)x_t \\ &= \sum_{i=0}^{+\infty} \pi_i x_{t-i}, \quad \text{with} \quad \sum_{i=0}^{+\infty} |\pi_i| < +\infty \end{aligned}$$

As in the previous case, if one considers the characteristic equation,

$$B(z) = z^q + b_1z^{q-1} + \dots + b_q = 0$$

then the $MA(q)$ process admits a causal autoregressive representation if the roots of the characteristic equation are strictly smaller than 1 in modulus.

Let's now consider, more in general, an ARMA process of order p, q . We say that a stationary process admits a minimal ARMA(p, q) representation if it can be written as

$$x_t + a_1x_{t-1} + a_px_{t-p} = b_1\varepsilon_t + \dots + b_q\varepsilon_{t-q}$$

or equivalently in terms of the lag operator

$$A(L)x_t = B(L)\varepsilon_t$$

where ε_t is a serially uncorrelated white noise with nonzero variance, $a_0 = b_0 = 1$, $a_p \neq 0$, $b_q \neq 0$, the polynomials A and B have roots strictly greater than 1 in modulus and do not have any root in common.

Generalizing the reasoning in the pure MA or AR case, it can be demonstrated that a generic process that admits the ARMA(p, q) representation $A(L)x_t = B(L)\varepsilon_t$ is stationary if both polynomials A and B have roots strictly different from 1. In addition, if all the roots of the polynomial $A(z)$ are strictly greater than 1 in modulus, then the ARMA(p, q) process can be expressed as a moving average process:

$$x_t = \frac{B(L)}{A(L)}\varepsilon_t$$

Conversely, if all the roots of the polynomial $B(z)$ are strictly greater than 1, then the ARMA(p, q) process can be expressed as an autoregressive process:

$$\varepsilon_t = \frac{A(L)}{B(L)}x_t$$

Note that in the above discussions every process was centered—that is, it had zero constant mean. As we were considering stationary processes, this condition is not restrictive as the eventual nonzero mean can be subtracted.

Note also that ARMA stationary processes extend through the entire time axis. An ARMA process, which begins from some initial conditions at starting time $t = 0$, is not stationary even if its roots are strictly outside the unit circle. It can be demonstrated, however, that such a process is asymptotically stationary.

Nonstationary Univariate ARMA Models

So far we have considered only stationary processes. However, ARMA equations can also represent nonstationary processes if some of the

roots of the polynomial $A(z)$ are equal to 1 in modulus. A process defined by the equation

$$A(L)x_t = B(L)\varepsilon_t$$

is called an *autoregressive integrated moving-average (ARIMA) process* if at least one of the roots of the polynomial A is equal to 1 in modulus. Suppose that λ be a root with multiplicity d . In this case the ARMA representation can be written as

$$A'(L)(I - \lambda L)^d x_t = B(L)\varepsilon_t$$

$$A(L) = A'(L)(I - \lambda L)^d$$

However this formulation is not satisfactory as the process A is not invertible if initial conditions are not provided; it is therefore preferable to offer a more rigorous definition, which includes initial conditions. Therefore, we give the following definition of nonstationary integrated ARMA processes.

A process x_t defined for $t \geq 0$ is called an *autoregressive integrated moving-average process—ARIMA(p, d, q)*—if it satisfies a relationship of the type

$$A(L)(I - \lambda L)^d x_t = B(L)\varepsilon_t$$

where:

- The polynomials $A(L)$ and $B(L)$ have roots strictly greater than 1.
- ε_t is a white noise process defined for $t \geq 0$.
- A set of initial conditions $(x_{-1}, \dots, x_{-p-d}, \varepsilon_t, \dots, \varepsilon_{-q})$ independent from the white noise is given.

Later in this entry we discuss the interpretation and further properties of the ARIMA condition.

Stationary Multivariate ARMA Models

Let's now move on to consider stationary multivariate processes. A stationary process that admits an infinite moving-average representation

of the type

$$x_t = \sum_{i=0}^{\infty} H_i \varepsilon_{t-i}$$

where ε_{t-i} is an n -dimensional, zero-mean, white-noise process with nonsingular variance-covariance matrix Ω is called an *autoregressive moving-average—ARMA(p, q)—model*, if it satisfies a difference equation of the type

$$A(L)x_t = B(L)\varepsilon_t$$

where A and B are matrix polynomials in the lag operator L of order p and q respectively:

$$A(L) = \sum_{i=0}^p A_i L^i, \quad A_0 = I, A_p \neq 0$$

$$B(L) = \sum_{j=0}^q B_j L^j, \quad B_0 = I, B_q \neq 0$$

If $q = 0$, the process is purely autoregressive of order p ; if $p = 0$, the process is purely a moving average of order q . Rearranging the terms of the difference equation, it is clear that an ARMA process is a process where the i -th component of the process at time t , $x_{i,t}$ is a linear function of all the components at different lags plus a finite moving average of white noise terms.

It can be demonstrated that the ARMA representation is not unique. The nonuniqueness of the ARMA representation is due to different reasons, such as the existence of a common polynomial factor in the autoregressive and the moving-average part. It entails that the same process can be represented by models with different pairs p, q . For this reason, one would need to determine at least a minimal representation—that is, an ARMA(p, q) representation such that any other ARMA(p', q') representation would have $p' > p, q' > q$. With the exception of the univariate case, these problems are very difficult from a mathematical point of view and we will not examine them in detail.

Let's now explore what restrictions on the polynomials $A(L)$ and $B(L)$ ensure that the relative ARMA process is stationary. Generalizing the univariate case, the mathematical analysis

of stationarity is based on the analysis of the polynomial $\det[\mathbf{A}(z)]$ obtained by formally replacing the lag operator L with a complex variable z in the matrix $\mathbf{A}(L)$ whose entries are finite polynomials in L .

It can be demonstrated that if the complex roots of the polynomial $\det[\mathbf{A}(z)]$, that is, the solutions of the algebraic equation $\det[\mathbf{A}(z)] = 0$, which are in general complex numbers, all lie outside the unit circle, that is, their modulus is strictly greater than one, then the process that satisfies the ARMA conditions,

$$\mathbf{A}(L)\mathbf{x}_t = \mathbf{B}(L)\boldsymbol{\varepsilon}_t$$

is stationary. As in the univariate case, if one would consider the equations in $1/z$, the same reasoning applies but with roots strictly inside the unit circle.

A stationary ARMA(p,q) process is an autocorrelated process. Its time-independent autocorrelation function satisfies a set of linear difference equations. Consider an ARMA(p,q) process that satisfies the following equation:

$$\mathbf{A}_0\mathbf{x}_t + \mathbf{A}_1\mathbf{x}_{t-1} + \dots + \mathbf{A}_p\mathbf{x}_{t-p} = \mathbf{B}_0\boldsymbol{\varepsilon}_t + \mathbf{B}_1\boldsymbol{\varepsilon}_{t-1} + \dots + \mathbf{B}_q\boldsymbol{\varepsilon}_{t-q}$$

where $\mathbf{A}_0 = \mathbf{I}$. By expanding the expression for the autocovariance function, it can be demonstrated that the autocovariance function satisfies the following set of linear difference equations:

$$\mathbf{A}_0\boldsymbol{\Gamma}_h + \mathbf{A}_1\boldsymbol{\Gamma}_{h-1} + \dots + \mathbf{A}_p\boldsymbol{\Gamma}_{h-p} = \begin{cases} 0 & \text{if } h > q \\ \sum_{j=0}^{q-h} \mathbf{B}_{j+h}\boldsymbol{\Omega}\mathbf{H}'_j & \text{if } h \leq q \end{cases}$$

where $\boldsymbol{\Omega}$ and \mathbf{H}_i are, respectively, the covariance matrix and the Markov coefficients of the process in its infinite moving-average representation:

$$\mathbf{x}_t = \sum_{i=0}^{\infty} \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i}$$

From the above representation, it is clear that if the process is purely MA, that is, if $p = 0$,

then the autocovariance function vanishes for lag $h > q$.

It is also possible to demonstrate the converse of this theorem. If a linear stationary process admits an autocovariance function that satisfies the following equations,

$$\mathbf{A}_0\boldsymbol{\Gamma}_h + \mathbf{A}_1\boldsymbol{\Gamma}_{h-1} + \dots + \mathbf{A}_p\boldsymbol{\Gamma}_{h-p} = 0 \quad \text{if } h > q$$

then the process admits an ARMA(p,q) representation. In particular, a stationary process is a purely finite moving-average process MA(q), if and only if its autocovariance functions vanish for $h > q$, where q is an integer.

Nonstationary Multivariate ARMA Models

Let's now consider nonstationary series. Consider a series defined for $t \geq 0$ that satisfies the following set of difference equations:

$$\mathbf{A}_0\mathbf{x}_t + \mathbf{A}_1\mathbf{x}_{t-1} + \dots + \mathbf{A}_p\mathbf{x}_{t-p} = \mathbf{B}_0\boldsymbol{\varepsilon}_t + \mathbf{B}_1\boldsymbol{\varepsilon}_{t-1} + \dots + \mathbf{B}_q\boldsymbol{\varepsilon}_{t-q}$$

where, as in the stationary case, $\boldsymbol{\varepsilon}_{t-i}$ is an n -dimensional zero-mean, white noise process with nonsingular variance-covariance matrix $\boldsymbol{\Omega}$, $\mathbf{A}_0 = \mathbf{I}$, $\mathbf{B}_0 = \mathbf{I}$, $\mathbf{A}_p \neq 0$, $\mathbf{B}_q \neq 0$. Suppose, in addition, that initial conditions ($\mathbf{x}_{-1}, \dots, \mathbf{x}_{-p}, \boldsymbol{\varepsilon}_t, \dots, \boldsymbol{\varepsilon}_{-q}$) are given. Under these conditions, we say that the process \mathbf{x}_t , which is well defined, admits an ARMA representation.

A process \mathbf{x}_t is said to admit an ARIMA representation if, in addition to the above, it satisfies the following two conditions: (1) $\det[\mathbf{B}(z)]$ has all its roots strictly outside of the unit circle, and (2) $\det[\mathbf{A}(z)]$ has all its roots outside the unit circle but with at least one root equal to 1. In other words, an ARIMA process is an ARMA process that satisfies some additional conditions. Later in this entry we will clarify the meaning of integrated processes.

Markov Coefficients and ARMA Models

For the theoretical analysis of ARMA processes, it is useful to state what conditions on the Markov coefficients ensure that the process admits an ARMA representation. Consider a process \mathbf{x}_t , stationary or not, which admits a moving-average representation either as

$$\mathbf{x}_t = \sum_{i=0}^{\infty} \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i}$$

or as a linear model:

$$\mathbf{x}_t = \sum_{i=0}^t \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i} + \mathbf{h}(t)\mathbf{z}$$

The process \mathbf{x}_t admits an ARMA representation if and only if there is an integer q and a set of p matrices $\mathbf{A}_i, i = 0, \dots, p$ such that the Markov coefficients \mathbf{H}_i satisfy the following linear difference equation starting from q :

$$\sum_{j=0}^p \mathbf{A}_j \mathbf{H}_{l-j} = 0, \quad l > q$$

Therefore, any ARMA process admits an infinite moving-average representation whose Markov coefficients satisfy a linear difference equation starting from a certain point. Conversely, any such linear infinite moving-average representation can be expressed parsimoniously in terms of an ARMA process.

Hankel Matrices and ARMA Models

For the theoretical analysis of ARMA processes it is also useful to restate the above conditions in terms of the Hankel infinite matrices. (A Hankel matrix is a matrix where for each antidiagonal the element is the same.) It can be demonstrated that a process, stationary or not, which admits either the infinite moving average representation

$$\mathbf{x}_t = \sum_{i=0}^{\infty} \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i}$$

or a linear moving average model

$$\mathbf{x}_t = \sum_{i=0}^t \mathbf{H}_i \boldsymbol{\varepsilon}_{t-i} + \mathbf{h}(t)\mathbf{z}$$

also admits an ARMA representation if and only if the Hankel matrix formed with the sequence of its Markov coefficients has finite rank or, equivalently, a finite column rank or row rank.

INTEGRATED SERIES AND TRENDS

This section introduces the fundamental notions of trend stationary series, difference stationary series, and integrated series. Consider a one-dimensional time series. A *trend stationary series* is a series formed by a deterministic trend plus a stationary process. It can be written as

$$X_t = f(t) + \varepsilon(t)$$

A trend stationary process can be transformed into a stationary process by subtracting the trend. Removing the deterministic trend entails that the deterministic trend is known. A trend stationary series is an example of an adjustment model.

Consider now a time series X_t . The operation of differencing a series consists of forming a new series $Y_t = \Delta X_t = X_t - X_{t-1}$. The operation of differencing can be repeated an arbitrary number of times. For instance, differencing twice the series X_t yields the following series:

$$\begin{aligned} Z_t &= \Delta Y_t = \Delta(\Delta X_t) \\ &= (X_t - X_{t-1}) - (X_{t-2} - X_{t-3}) \\ &= X_t - X_{t-1} - X_{t-2} + X_{t-3} \end{aligned}$$

Differencing can be written in terms of the lag operator as

$$\Delta X_t^d = (1 - L)^d X_t$$

A difference stationary series is a series that is transformed into a stationary series by differencing. A difference stationary series can be

written as

$$\Delta X_t = \mu + \varepsilon(t)$$

$$X_t = X_{t-1} + \mu + \varepsilon(t)$$

where $\varepsilon(t)$ is a zero-mean stationary process and μ is a constant. A trend stationary series with a linear trend is also difference stationary, if spacings are regular. The opposite is not generally true. A time series is said to be integrated of order n if it can be transformed into a stationary series by differencing n times.

Note that the concept of integrated series as defined above entails that a series extends on the entire time axis. If a series starts from a set of initial conditions, the difference sequence can only be asymptotically stationary.

There are a number of obvious differences between trend stationary and difference stationary series. A trend stationary series experiences stationary fluctuation, with constant variance, around an arbitrary trend. A difference stationary series meanders arbitrarily far from a linear trend, producing fluctuations of growing variance. The simplest example of difference stationary series is the random walk.

An integrated series is characterized by a stochastic trend. In fact, a difference stationary series can be written as

$$X_t = \mu t + \left[\sum_{s=0}^{t-1} \varepsilon(s) \right] + \varepsilon(t)$$

The difference $X_t - X_t^*$ between the value of a process at time t and the best affine prediction at time $t - 1$ is called the innovation of the process. In the above linear equation, the stationary process $\varepsilon(t)$ is the innovation process. A key aspect of integrated processes is that innovations $\varepsilon(t)$ never decay but keep on accumulating. In a trend stationary process, on the other hand, past innovations disappear at every new step.

These considerations carry over immediately in a multidimensional environment. Multidimensional trend stationary series will exhibit multiple trends, in principle one for

each component. Multidimensional difference-stationary series will yield a stationary process after differencing.

Let's now see how these concepts fit into the ARMA framework, starting with univariate ARMA model. Recall that an ARIMA process is defined as an ARMA process in which the polynomial B has all roots outside the unit circle while the polynomial A has one or more roots equal to 1. In the latter case the process can be written as

$$A'(L)\Delta^d x_t = B(L)\varepsilon_t$$

$$A(L) = (1 - L)^d A'(L)$$

and we say that the process is integrated of order n . If initial conditions are supplied, the process can be inverted and the difference sequence is asymptotically stationary.

The notion of integrated processes carries over naturally in the multivariate case but with a subtle difference. Recall from earlier discussion in this entry that an ARIMA model is an ARMA model:

$$\mathbf{A}(L)\mathbf{x}_t = \mathbf{B}(L)\varepsilon_t$$

which satisfies two additional conditions: (1) $\det[\mathbf{B}(z)]$ has all its roots strictly outside of the unit circle, and (2) $\det[\mathbf{A}(z)]$ has all its roots outside the unit circle but with at least one root equal to 1.

Now suppose that, after differencing d times, the multivariate series $\Delta^d \mathbf{x}_t$ can be represented as follows:

$$\mathbf{A}'(L)\mathbf{x}_t = \mathbf{B}'(L)\varepsilon_t, 1 \quad \text{with} \quad \mathbf{A}'(L) = \mathbf{A}(L)\Delta^d$$

In this case, if (1) $\mathbf{B}'(z)$ is of order q and $\det[\mathbf{B}'(z)]$ has all its roots strictly outside of the unit circle and (2) $\mathbf{A}'(z)$ is of order p and $\det[\mathbf{A}'(z)]$ has all its roots outside the unit circle, then the process is called ARIMA(p, d, q). Not all ARIMA models can be put in this framework as different components might have a different order of integration.

Note that in an ARIMA(p, d, q) model each component series of the multivariate model is individually integrated. A multivariate series is

integrated of order d if every component series is integrated of order d .

Note also that ARIMA processes are not invertible as infinite moving averages, but as discussed, they can be inverted in terms of a generic linear moving-average model with stochastic initial conditions. In addition, the process in the d -differences is asymptotically stationary.

In both trend stationary and difference stationary processes, innovations can be serially autocorrelated. In the ARMA representations discussed in the previous section, innovations are serially uncorrelated white noise as all the autocorrelations are assumed to be modeled in the ARMA model. If there is residual autocorrelation, the ARMA or ARIMA model is somehow misspecified.

The notion of an integrated process is essentially linear. A process is integrated if stationary innovations keep on adding indefinitely. Note that innovations could, however, cumulate in ways other than addition, producing essentially nonlinear processes. In ARCH and GARCH processes for instance, innovations do not simply add to past innovations.

The behavior of integrated and nonintegrated time series is quite different and the estimation procedures are different as well. It is therefore important to ascertain if a series is integrated or not. Often a preliminary analysis to ascertain integratedness suggests what type of model should be used.

A number of statistical tests to ascertain if a univariate series is integrated are available. Perhaps the most widely used and known are the Dickey-Fuller (DF) and the Augmented Dickey-Fuller (ADF) tests. The DF test assumes as a null hypothesis that the series is integrated of order 1 with uncorrelated innovations. Under this assumption, the series can be written as a random walk in the following form:

$$\begin{aligned} X_{t+1} &= \rho X_t + b + \varepsilon_t \\ \rho &= 1 \\ \varepsilon_t &\text{ IID} \end{aligned}$$

where IID is an independent and identical sequence.

In a sample generated by a model of this type, the value of ρ estimated on the sample is stochastic. Estimation can be performed with the ordinary least square (OLS) method. Dickey and Fuller determined the theoretical distribution of ρ and computed the critical values of ρ that correspond to different confidence intervals. The theoretical distribution of ρ is determined computing a functional of the Brownian motion.

Given a sample of a series, for instance a series of log prices, application of the DF test entails computing the autoregressive parameter ρ on the given sample and comparing it with the known critical values for different confidence intervals. The strict hypothesis of random walk is too strong for most econometric applications. The DF test was extended to cover the case of correlated residuals that are modeled as a linear model. In the latter case, the DF test is called the Augmented Dickey-Fuller or ADF test. The Phillips and Perron test is the DF test in the general case of autocorrelated residuals.

APPENDIX

We will begin with several concepts from probability theory.

Stochastic Processes

When it is necessary to emphasize the dependence of the random variable from both time t and the element ω , a stochastic process is explicitly written as a function of two variables: $X = X(t, \omega)$. Given ω , the function $X = X_t(\omega)$ is a function of time that is referred to as the path of the stochastic process.

The variable X might be a single random variable or a multidimensional random vector. A stochastic process is therefore a function $X = X(t, \omega)$ from the product space $[0, T] \times \Omega$ into the n -dimensional real space R^n . Because to each ω corresponds a time path of the process—in

general formed by a set of functions $X = X_t(\omega)$ —it is possible to identify the space Ω with a subset of the real functions defined over an interval $[0, T]$.

Let's now discuss how to represent a stochastic process $X = X(t, \omega)$ and the conditions of identity of two *stochastic processes*. As a stochastic process is a function of two variables, we can define equality as pointwise identity for each couple (t, ω) . However, as processes are defined over probability spaces, pointwise identity is seldom used. It is more fruitful to define equality modulo sets of measure zero or equality with respect to probability distributions. In general, two random variables X, Y will be considered equal if the equality $X(\omega) = Y(\omega)$ holds for every ω with the exception of a set of probability zero. In this case, it is said that the equality holds almost everywhere (denoted *a.e.*).

A rather general (but not complete) representation is given by the finite dimensional probability distributions. Given any set of indices t_1, \dots, t_m , consider the distributions

$$\mu_{t_1, \dots, t_m}(H) = P[(X_{t_1}, \dots, X_{t_m}) \in H, H \in \mathfrak{B}^n]$$

These probability measures are, for any choice of the t_i , the finite-dimensional joint probabilities of the process. They determine many, but not all, properties of a stochastic process. For example, the finite dimensional distributions of a Brownian motion do not determine whether or not the process paths are continuous.

In general, the various concepts of equality between stochastic processes can be described as follows:

- *Property 1.* Two stochastic processes are weakly equivalent if they have the same finite-dimensional distributions. This is the weakest form of equality.
- *Property 2.* The process $X = X(t, \omega)$ is said to be equivalent or to be a modification of the process $Y = Y(t, \omega)$ if, for all t ,

$$P(X_t = Y_t) = 1$$

- *Property 3.* The process $X = X(t, \omega)$ is said to be strongly equivalent to or indistinguishable from the process $Y = Y(t, \omega)$ if

$$P(X_t = Y_t, \text{ for all } t) = 1$$

Property 3 implies Property 2, which in turn implies Property 1. Implications do not hold in the opposite direction. Two processes having the same finite distributions might have completely different paths. However it is possible to demonstrate that if one assumes that paths are continuous functions of time, Properties 2 and 3 become equivalent.

Information Structures

Let's now turn our attention to the question of time. We must introduce an appropriate representation of time as well as rules that describe the evolution of information, that is, information propagation, over time. The concepts of information and information propagation are fundamental in economics and finance theory.

The concept of information in finance is different from both the intuitive notion of information and that of information theory in which information is a quantitative measure related to the *a priori* probability of messages. In our context, information means the (progressive) revelation of the set of events to which the current state of the economy belongs. Though somewhat technical, this concept of information sheds light on the probabilistic structure of finance theory. The point is the following. Assets are represented by stochastic processes, that is, time-dependent random variables. But the probabilistic states on which these random variables are defined represent entire histories of the economy. To embed time into the probabilistic structure of states in a coherent way calls for information structures and filtrations (a concept we explain next).

It is assumed that the economy is in one of many possible states and that there is uncertainty on the state that has been realized.

Consider a time period of the economy. At the beginning of the period, there is complete uncertainty on the state of the economy (i.e., there is complete uncertainty on what path the economy will take). Different events have different probabilities, but there is no certainty. As time passes, uncertainty is reduced as the number of states to which the economy can belong is progressively reduced. Intuitively, revelation of information means the progressive reduction of the number of possible states; at the end of the period, the realized state is fully revealed. In continuous time and continuous states, the number of events is infinite at each instant. Thus its cardinality remains the same. We cannot properly say that the number of events shrinks. A more formal definition is required.

The progressive reduction of the set of possible states is formally expressed in the concepts of information structure and filtration. Let's start with *information structures*. Information structures apply only to discrete probabilities defined over a discrete set of states. At the initial instant T_0 , there is complete uncertainty on the state of the economy; the actual state is known only to belong to the largest possible event (that is, the entire space Ω). At the following instant T_1 , assuming that instants are discrete, the states are separated into a partition, a partition being a denumerable class of disjoint sets whose union is the space itself. The actual state belongs to one of the sets of the partitions. The revelation of information consists in ruling out all sets but one. For all the states of each partition, and only for these, random variables assume the same values.

Suppose, to exemplify, that only two assets exist in the economy and that each can assume only two possible prices and pay only two possible cash flows. At every moment there are 16 possible price-cash flow combinations. We can thus see that at the moment T_1 all the states are partitioned into 16 sets, each containing only one state. Each partition includes all the states that have a given set of prices and cash distributions at the moment T_1 . The same reasoning

can be applied to each instant. The evolution of information can thus be represented by a tree structure in which every path represents a state and every point a partition. Obviously the tree structure does not have to develop as symmetrically as in the above example; the tree might have a very generic structure of branches.

Filtration

The concept of information structure based on partitions provides a rather intuitive representation of the propagation of information through a tree of progressively finer partitions. However, this structure is not sufficient to describe the propagation of information in a general probabilistic context. In fact, the set of possible events is much richer than the set of partitions. It is therefore necessary to identify not only partitions but also a structure of events. The structure of events used to define the propagation of information is called a *filtration*. In the discrete case, however, the two concepts—information structure and filtration—are equivalent.

The concept of filtration is based on identifying all events that are known at any given instant. It is assumed that it is possible to associate to each trading moment t a σ -algebra of events $\mathfrak{F}_t \subset \mathfrak{F}$ formed by all events that are known prior to or at time t . It is assumed that events are never “forgotten,” that is, that $\mathfrak{F}_t \subset \mathfrak{F}_s$, if $t < s$. An ordering of time is thus created. This ordering is formed by an increasing sequence of σ -algebras, each associated to the time at which all its events are known. This sequence is a filtration. Indicated as $\{\mathfrak{F}_t\}$, a filtration is therefore an increasing sequence of all σ -algebras \mathfrak{F}_t , each associated to an instant t .

In the finite case, it is possible to create a mutual correspondence between filtrations and information structures. In fact, given an information structure, it is possible to associate to each partition the algebra generated by the same partition. Observe that a tree information structure is formed by partitions that create

increasing refinement: By going from one instant to the next, every set of the partition is decomposed. One can then conclude that the algebras generated by an information structure form a filtration.

On the other hand, given a filtration $\{\mathfrak{J}_t\}$, it is possible to associate a partition to each \mathfrak{J}_t . In fact, given any element that belongs to Ω , consider any other element that belongs to Ω such that, for each set of \mathfrak{J}_t , both either belong to or are outside this set. It is easy to see that classes of equivalence are thus formed, that these create a partition, and that the algebra generated by each such partition is precisely the \mathfrak{J}_t that has generated the partition.

A stochastic process is said to be adapted to the filtration $\{\mathfrak{J}_t\}$ if the variable X_t is measurable with respect to the σ -algebra \mathfrak{J}_t . It is assumed that the price and cash distribution processes $S_t(\omega)$ and $d_t(\omega)$ of every asset are adapted to $\{\mathfrak{J}_t\}$. This means that, for each t , no measurement of any price or cash distribution variable can identify events not included in the respective algebra or σ -algebra. Every random variable is a partial image of the set of states seen from a given point of view and at a given moment.

The concepts of filtration and of processes adapted to a filtration are fundamental. They ensure that information is revealed without anticipation. Consider the economy and associate at every instant a partition and an algebra generated by the partition. Every random variable defined at that moment assumes a value constant on each set of the partition. The knowledge of the realized values of the random variables does not allow identifying sets of events finer than partitions.

One might well ask: Why introduce the complex structure of σ -algebras as opposed to simply defining random variables? The point is that, from a logical point of view, the primitive concept is that of states and events. The evolution of time has to be defined on the primitive structure—it cannot simply be imposed on random variables. In practice, filtrations be-

come an important concept when dealing with conditional probabilities in a continuous environment. As the probability that a continuous random variable assumes a specific value is zero, the definition of conditional probabilities requires the machinery of filtration.

Conditional Probability and Conditional Expectation

Conditional probabilities and conditional averages are fundamental in the stochastic description of financial markets. For instance, one is generally interested in the probability distribution of the price of an asset at some date given its price at an earlier date. The widely used regression models are an example of conditional expectation models.

The *conditional probability* of event A given event B was defined earlier as

$$P(A|B) = \frac{P(A \cap B)}{P(B)}$$

This simple definition cannot be used in the context of continuous random variables because the conditioning event (i.e., one variable assuming a given value) has probability zero. To avoid this problem, we condition on σ -algebras and not on single zero-probability events. In general, as each instant is characterized by a σ -algebra \mathfrak{J}_t , the conditioning elements are the \mathfrak{J}_t .

The general definition of *conditional expectation* is the following. Consider a probability space $(\Omega, \mathfrak{J}, P)$ and a σ -algebra \mathfrak{G} contained in \mathfrak{J} and suppose that X is an integrable random variable on $(\Omega, \mathfrak{J}, P)$. We define the conditional expectation of X with respect to \mathfrak{G} , written as $E[X|\mathfrak{G}]$, as a random variable measurable with respect to \mathfrak{G} such that

$$\int_G E[X|\mathfrak{G}] dP$$

for every set $G \in \mathfrak{G}$. In other words, the *conditional expectation* is a random variable whose average on every event that belongs to \mathfrak{G} is equal to the average of X over those same events, but

it is \mathcal{G} -measurable while X is not. It is possible to demonstrate that such variables exist and are unique up to a set of measure zero.

Econometric models usually condition a random variable given another variable. In the previous framework, conditioning one random variable X with respect to another random variable Y means conditioning X given $\sigma\{Y\}$ (i.e., given the σ -algebra generated by Y). Thus $E[X|Y]$ means $E[X|\sigma\{Y\}]$.

This notion might seem to be abstract and to miss a key aspect of conditioning: intuitively, conditional expectation is a function of the conditioning variable. For example, given a stochastic price process, X_t , one would like to visualize conditional expectation $E[X_t | X_s]$, $s < t$ as a function of X_s that yields the expected price at a future date given the present price. This intuition is not wrong insofar as the conditional expectation $E[X|Y]$ of X given Y is a random variable function of Y .

However, we need to specify how conditional expectations are formed, given that the usual conditional probabilities cannot be applied as the conditioning event has probability zero. Here is where the above definition comes into play. The conditional expectation of a variable X given a variable Y is defined in full generality as a variable that is measurable with respect to the σ -algebra $\sigma(Y)$ generated by the conditioning variable Y and has the same expected value of Y on each set of $\sigma(Y)$. Later in this section we will see how conditional expectations can be expressed in terms of the joint p.d.f. of the conditioning and conditioned variables.

One can define conditional probabilities starting from the concept of conditional expectations. Consider a probability space $(\Omega, \mathfrak{J}, P)$, a sub- σ -algebra \mathcal{G} of \mathfrak{J} , and two events $A \in \mathfrak{J}$, $B \in \mathfrak{J}$. If I_A, I_B are the indicator functions of the sets A, B (the indicator function of a set assumes value 1 on the set, 0 elsewhere), we can define conditional probabilities of the event A , respectively, given \mathcal{G} or given the event B as

$$P(A|\mathcal{G}) = E[I_A|\mathcal{G}] \quad P(A|B) = E[I_A|I_B]$$

Using these definitions, it is possible to demonstrate that given two random variables X and Y with joint density $f(x, y)$, the conditional density of X given Y is

$$f(x|y) = \frac{f(x, y)}{f_Y(y)}$$

where the marginal density, defined as

$$f_Y(y) = \int_{-\infty}^{\infty} f(x, y) dx$$

is assumed to be strictly positive.

In the discrete case, the conditional expectation is a random variable that takes a constant value over the sets of the finite partition associated to \mathfrak{J}_t . Its value for each element of Ω is defined by the classical concept of conditional probability. Conditional expectation is simply the average over a partition assuming the classical conditional probabilities.

An important econometric concept related to conditional expectations is that of a martingale. Given a probability space $(\Omega, \mathfrak{J}, P)$ and a filtration $\{\mathfrak{J}_t\}$, a sequence of \mathfrak{J}_t -measurable random variables X_t is called a martingale if the following condition holds:

$$E[X_{t+1}|\mathfrak{J}_t] = X_t$$

A martingale translates the idea of a “fair game” as the expected value of the variable at the next period is the present value of the same value.

KEY POINTS

- Stochastic processes are time-dependent random variables.
- An information structure is a collection of partitions of events associated to each instant of time that become progressively finer with the evolution of time. A filtration is an increasing collection of σ -algebras associated to each instant of time.
- The states of the economy, intended as full histories of the economy, are represented as a

probability space. The revelation of information with time is represented by information structures or filtrations. Prices and other financial quantities are represented by adapted stochastic processes.

- By conditioning is meant the change in probabilities due to the acquisition of some information. It is possible to condition with respect to an event if the event has nonzero probability. In general terms, conditioning means conditioning with respect to a filtration or an information structure.
- A martingale is a stochastic process such that the conditional expected value is always equal to its present value. It embodies the idea of a fair game where today's wealth is the best forecast of future wealth.
- A time series is a discrete-time stochastic process, that is, a denumerable collection of random variables indexed by integer numbers.
- Any stationary time series admits an infinite moving average representation, that is to say, it can be represented as an infinite sum of white noise terms with appropriate coefficients.
- A time series is said to be invertible if it can also be represented as an infinite autoregression, that is, an infinite sum of all past terms with appropriate coefficients.

- ARMA models are parsimonious representations that involve only a finite number of moving average and autoregressive terms.
- An ARMA model is stationary if all the roots of the inverse characteristic equation of the AR or the MA part have roots with modulus strictly greater than one.
- A process is said to be integrated of order p if it becomes stationary after differencing p times.

Extracting Risk-Neutral Density Information from Options Market Prices

ARTURO LECCADITO, PhD

Business Administration Department, Università della Calabria

RADU TUNARU, PhD

Professor of Quantitative Finance, Business School, University of Kent

Abstract: Information on risk-neutral density is valuable in financial markets for a wide range of participants. This density can be used to mark-to-market exotic options that are not very liquid on the market, for anticipation of effects determined by new policy or possible extreme events such as crashes, and even for designing new trading strategies. There are many models that have been proposed in the past for estimating the risk-neutral density, each with their pros and cons.

The concept of *risk-neutral density* (RND) plays an important theoretical role in asset pricing as outlined in Cox and Ross (1976), published very shortly after the publication of the Black-Scholes model. Since then, the estimation of RND has become an essential tool for central banks in monitoring the stability of the financial system and for measuring the impact of new policies. Investment banks also rely on the RND calibrated from liquid European vanilla options to determine the price of more exotic positions on their balance sheet that are not very liquid. Moreover, the first moments of the RND, such as implied volatility and skewness, can be used to design trading strategies.

One may argue that the information contained in option prices is redundant to the information provided by historical prices of

the underlying asset. However, based on the 1987 stock market crash, Jackwerth and Rubinstein (1996) demonstrated that this is not the case. Prior to the crash, the RND estimated at one-month horizon had been close to lognormal but subsequently the shape of the RND changed considerably. At the same time, they also revealed that the historical distribution had been lognormal and it remained like that after the crash. In other words, the option prices in the equity market contain different information from the historical equity prices.

In this entry we highlight the main steps for estimating the RND associated with an equity index. We exemplify the estimation procedure by applying a model based on both the *generalized inverse Gaussian distribution* that has been advocated in the literature for financial

modeling and the well-known lognormal mixture model that has been widely used by investment houses and central banks. These two models are straightforward and easy to apply since the option pricing formulas can be derived in closed form.

AN APPROPRIATE PARAMETRIC MODEL

The RND is recovered from a bundle of European vanilla call and put option prices on the same underlying asset X and with the same maturity T . The options differ in the exercise price K . Denoting with $f(\cdot)$ the probability density function of the underlying asset X under the risk-neutral probability measure \mathbb{Q} , the European vanilla call price for strike K is

$$C(K) = e^{-rT} \int_K^{\infty} (X_T - K) f(X_T) dX_T \quad (1)$$

where r is the continuous compounding risk-free rate.

The partial derivative of 1 with respect to the strike price K

$$\begin{aligned} \frac{\partial C}{\partial K} &= e^{-rT} \frac{\partial}{\partial K} \left[\int_K^{\infty} (X_T - K) f(X_T) dX_T \right] \\ &= -e^{-rT} \int_K^{\infty} f(X_T) dX_T = -e^{-rT} [1 - F(K)] \end{aligned}$$

where $F(\cdot)$ is the cumulative distribution function under the risk-neutral measure. Thus

$$F(K) = e^{rT} \frac{\partial C}{\partial K} + 1 \quad (2)$$

The RND probability function f can be obtained by derivation of the cumulative function F

$$f(K) = e^{rT} \frac{\partial^2 C}{\partial K^2} \quad (3)$$

One could then try to reconstruct either F or f from a grid of option prices using finite difference schemes. However, such numerical methods are notoriously unreliable and very sensitive to the sample of option prices available.

Over the years, two main classes of methods have emerged. First, parametric methods are

underpinned by univariate distributions such as the Weibull distribution (see Savickas, 2002, 2005), the generalized beta distribution (see McDonald and Xu, 1995; Anagnou et al., 2005), the generalized lambda distribution (see Corrado, 2001), the generalized gamma distribution (see Albota et al., 2009), the g-and-h distribution as proposed by Dutta and Babbel (2005); and a mixture of univariate distributions such as that proposed by Gemmill and Saflekos (2000) for two lognormals, and Melick and Thomas (1997) for three lognormals.

The second class is defined by semiparametric and nonparametric methods such as (1) expansion methods as used by Jarrow and Rudd (1982) and Corrado and Su (1997), (2) direct fitting of the implied volatility curve with splines or other interpolation methods as described by Shimko (1993), Anagnou et al. (2003), and Brunner and Hafner (2003), (3) kernel methods developed in Ait-Sahalia and Lo (1998) and Ait-Sahalia and Duarte (2003), and (4) maximum entropy methods as applied by Buchen and Kelly (1996) and Avellaneda (1998).

The nonparametric approach usually requires a large sample of data in order to achieve a good fit. In financial markets, for many asset classes, large samples may simply not be available. In this entry, we focus on the fully parametric approach.

The strategy for parametric models represented by a vector of parameters θ is to minimize some type of discrepancy measure between the theoretical options prices and the observed market prices.

Given the availability of N European call options $\{C(K_{i_j})\}_{j=1,\dots,N}$ and M put options $\{P(K_{s_j})\}_{j=1,\dots,M}$, all with the same maturity T , the problem that must be solved is the minimization of the function

$$\begin{aligned} H_1(\theta) &= \sum_{j=1}^N [C(K_{i_j}) - C^{mkt}(K_{i_j})]^2 \\ &+ \sum_{j=1}^M [P(K_{s_j}) - P^{mkt}(K_{s_j})]^2 \quad (4) \end{aligned}$$

subject to the forward constraint $\mathbb{E}^{\mathbb{Q}}[X_T] = F_0$, where F_0 is the forward price on the same underlying asset X and the last term of the sum accounts for the forward martingale condition that must be satisfied for any parametric model. The notation C^{mkt} , and P^{mkt} , relates, respectively, to the actual option prices from the market. The function H is a discrepancy measure between the theoretical prices obtained under the chosen parametric RND $f(\cdot; \theta)$ and the market prices.

While the H in (4) is widely used in practice, it is sometimes useful to consider other potential discrepancy measures such as

$$\begin{aligned} H_2(\theta) &= \sum_{j=1}^N \frac{[C(K_{i_j}) - C^{mkt}(K_{i_j})]^2}{C^{mkt}(K_{i_j})} \\ &\quad + \sum_{j=1}^M \frac{[P(K_{s_j}) - P^{mkt}(K_{s_j})]^2}{P^{mkt}(K_{s_j})} \\ H_3(\theta) &= \sum_{j=1}^N \frac{[C(K_{i_j}) - C^{mkt}(K_{i_j})]^2}{C(K_{i_j})} \\ &\quad + \sum_{j=1}^M \frac{[P(K_{s_j}) - P^{mkt}(K_{s_j})]^2}{P(K_{s_j})} \\ H_4(\theta) &= \sum_{j=1}^N |[C(K_{i_j}) - C^{mkt}(K_{i_j})]| \\ &\quad + \sum_{j=1}^M |[P(K_{s_j}) - P^{mkt}(K_{s_j})]| \end{aligned}$$

Since the market option prices that do not satisfy put-call parity are filtered out of the data used for calibration, it is possible to work with call prices only or with put prices only, if that is more convenient numerically.

TWO PARAMETRIC MODELS FOR RND ESTIMATION

In order to be able to reverse engineer the RND from options prices, a pricing formula for European vanilla options under the chosen distribution is needed. There is a great advantage in having the pricing formulas in closed form, other-

wise numerical integral approximation methods must be employed and this means that there is a risk of introducing errors in the estimation procedure.

Here we illustrate the RND estimation procedure for two special cases, the general inverse Gaussian (GIG) distribution and the lognormal mixture (LnMix) distribution. For both models, closed-form solutions for pricing European options are available.

Pricing Options with the GIG Distribution

The GIG distribution has been advocated for applications in financial modeling due to its flexibility to fit heavy tails (see Bibby and Sorensen, 2003). The probability density function of the GIG distribution is¹

$$f_{\text{GIG}}(x; \lambda, \chi, \psi) = \frac{x^{\lambda-1} \exp[-\frac{1}{2}(\chi x^{-1} + \psi x)]}{k_{\lambda}(\chi, \psi)} \times I_{(0, \infty)}(x) \quad (5)$$

where

$$k_{\lambda}(\chi, \psi) = \int_0^{\infty} x^{\lambda-1} \exp\left[-\frac{1}{2}(\chi x^{-1} + \psi x)\right] dx$$

is a normalizing constant that is related to the modified Bessel function of the third kind,

$$K_{\nu}(z) = \frac{1}{2} \int_0^{\infty} t^{\nu-1} \exp\left[-\frac{z}{2}(t^{-1} + t)\right] dt \quad (6)$$

via

$$k_{\lambda}(\chi, \psi) = 2 \left(\frac{\chi}{\psi}\right)^{\lambda/2} K_{\lambda}(\sqrt{\chi\psi}) \quad (7)$$

Further technical details on this distribution can be found in Paoletta (2007).

The GIG distribution is well defined, or "proper," for the parameter domain

$$\{(\lambda, \chi, \psi) \in \mathbb{R} \times (0, \infty) \times (0, \infty)\}$$

There are also two boundary cases possible: (1) $\lambda > 0$, $\chi = 0$ and $\psi > 0$ and (2) $\lambda < 0$, $\chi > 0$

and $\psi = 0$. Applying some standard algebraic routine leads to

$$\begin{aligned}
 P(K) &= Ke^{-rT} F_{GIG}(K; \lambda, \chi, \psi) \\
 &\quad - e^{-rT} \int_0^K x F_{GIG}(x; \lambda, \chi, \psi) dx \\
 &= Ke^{-rT} F_{GIG}(K; \lambda, \chi, \psi) \\
 &\quad - e^{-rT} \frac{k_{\lambda+1}(\chi, \psi)}{k_{\lambda}(\chi, \psi)} \\
 &\quad \times \int_0^K f_{GIG}(x; \lambda + 1, \chi, \psi) dx \\
 &= Ke^{-rT} F_{GIG}(K; \lambda, \chi, \psi) \\
 &\quad - e^{-rT} \sqrt{\frac{\chi}{\psi}} \frac{K_{\lambda+1}(\sqrt{\chi\psi})}{K_{\lambda}(\sqrt{\chi\psi})} \\
 &\quad \times F_{GIG}(K; \lambda + 1, \chi, \psi)
 \end{aligned}$$

This formula can be rewritten in terms of the forward price $F_0 = \mathbb{E}^Q(X_T)$ as

$$\begin{aligned}
 P(K) &= Ke^{-rT} F_{GIG}(K; \lambda, \chi, \psi) \\
 &\quad - F_0 e^{-rT} F_{GIG}(K; \lambda + 1, \chi, \psi) \quad (8)
 \end{aligned}$$

RND Estimation with the LnMix Distribution

The importance of fat tails and non-normal distributions in modeling equity stock and vanilla options has become prominent in the aftermath of the Black Monday 1987 crisis. The LnMix model is a convex combination of several lognormal individual models. Bahra (1997) was the first to propose using the LnMix model for RND estimation. An exact solution for options pricing of vanilla European call and put options

can be derived as a weighted sum of standard Black-Scholes prices. In practice, the preferred mixture model is the one based on two individual lognormal models.

If $LN(x; \alpha, \beta)$ is the lognormal distribution with parameters α and β , then the LnMix distribution is given by the following probability density function

$$\begin{aligned}
 f_{LN}(x; \alpha_1, \beta_1, \alpha_2, \beta_2, \eta) &= \eta LN(x; \alpha_1, \beta_1) \\
 &\quad + (1 - \eta) LN(x; \alpha_2, \beta_2) \quad (9)
 \end{aligned}$$

Bahra (1997) described the formulas for pricing European vanilla call and put options

$$\begin{aligned}
 C(K) &= e^{-rT} \{ \eta [e^{(\alpha_1 + 0.5\beta_1^2)} N(d_1) - KN(d_2)] \\
 &\quad + (1 - \eta) [e^{(\alpha_2 + 0.5\beta_2^2)} N(d_3) - KN(d_4)] \} \\
 P(K) &= e^{-rT} \{ \eta [e^{(\alpha_1 + 0.5\beta_1^2)} N(d_1) - KN(d_2)] \\
 &\quad + (1 - \eta) [e^{(\alpha_2 + 0.5\beta_2^2)} N(d_3) - KN(d_4)] \}
 \end{aligned}$$

where

$$\begin{aligned}
 d_1 &= \frac{\alpha_1 + \beta_1^2 - \log(K)}{\beta_1}, & d_2 &= d_1 - \beta_1 \\
 d_3 &= \frac{\alpha_2 + \beta_2^2 - \log(K)}{\beta_2}, & d_4 &= d_3 - \beta_2
 \end{aligned}$$

and N is the standard normal cumulative distribution function.

This model has five parameters $\alpha_1, \beta_1, \alpha_2, \beta_2,$ and η and one should expect a better fit of data with this model compared to the GIG model that has only three parameters. If the *calibration* goodness-of-fit results are very similar between the two models, then the model with fewer parameters should be preferred based on the principle of parsimony.

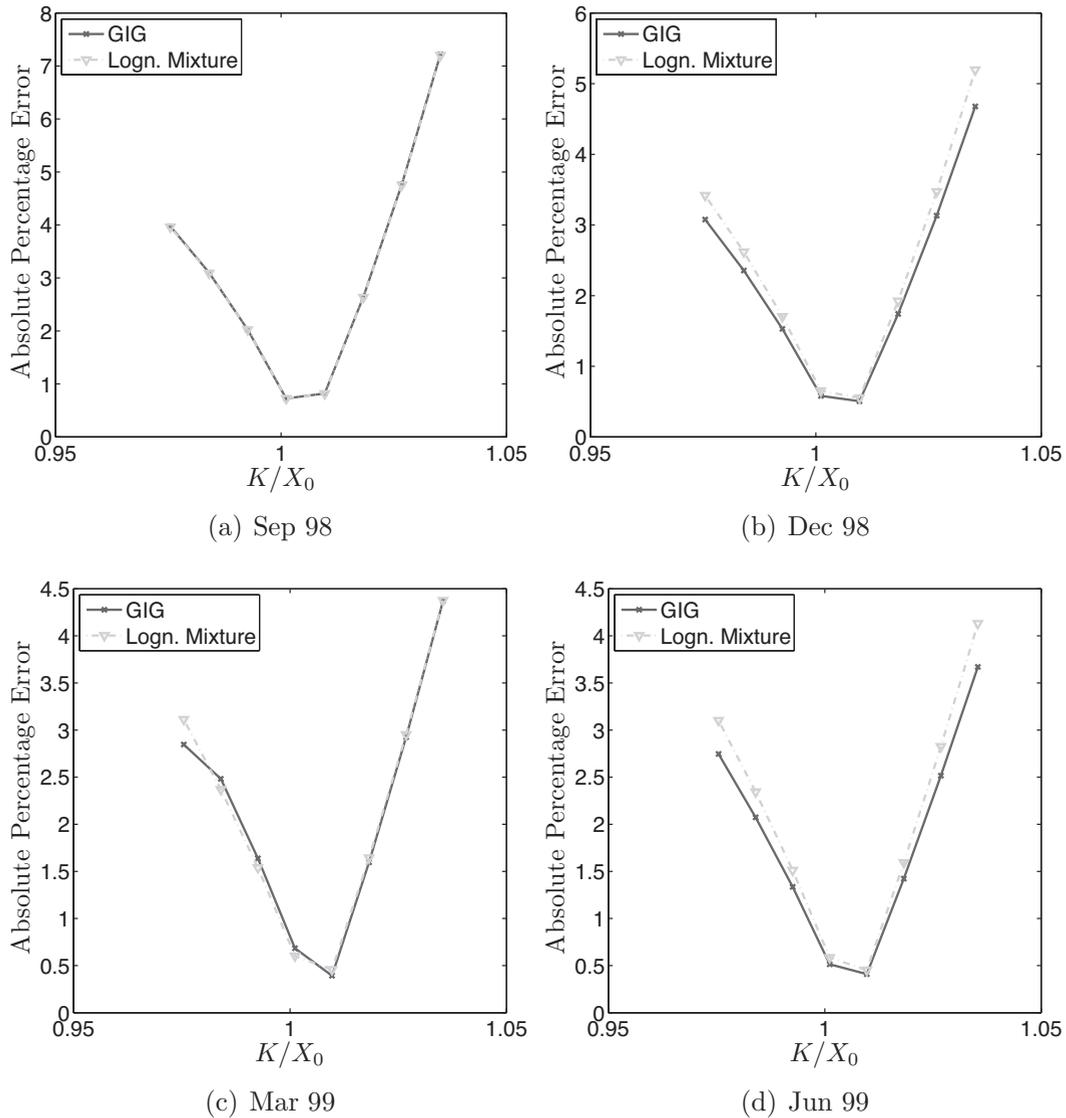

Figure 1 Absolute Percentage Errors for the First Four Maturities

FITTING THE MODELS TO DATA

For the RND estimation with a parametric model, the main elements are (1) formulas for pricing either European call or European put options, together with a formula for the forward price, (2) a minimization procedure for a non-linear function such as H_1 in the function given by (4), and (3) a set of market option prices.

Here we illustrate the calibration of the GIG and LnMix models using a dataset reported in Table 1, which is described in Rebonato (2004, pp. 290–291), and it is a typical example for the UK equity market.

The goodness of fit of the two models can be assessed to some extent from the results in Table 2, which reports the values obtained for the sum of squared residual $H_1(\hat{\theta}; \mathbf{m})$, where $\hat{\theta} = \arg \min_{\theta} H_1(\theta; \mathbf{m})$ and \mathbf{m} is the vector with

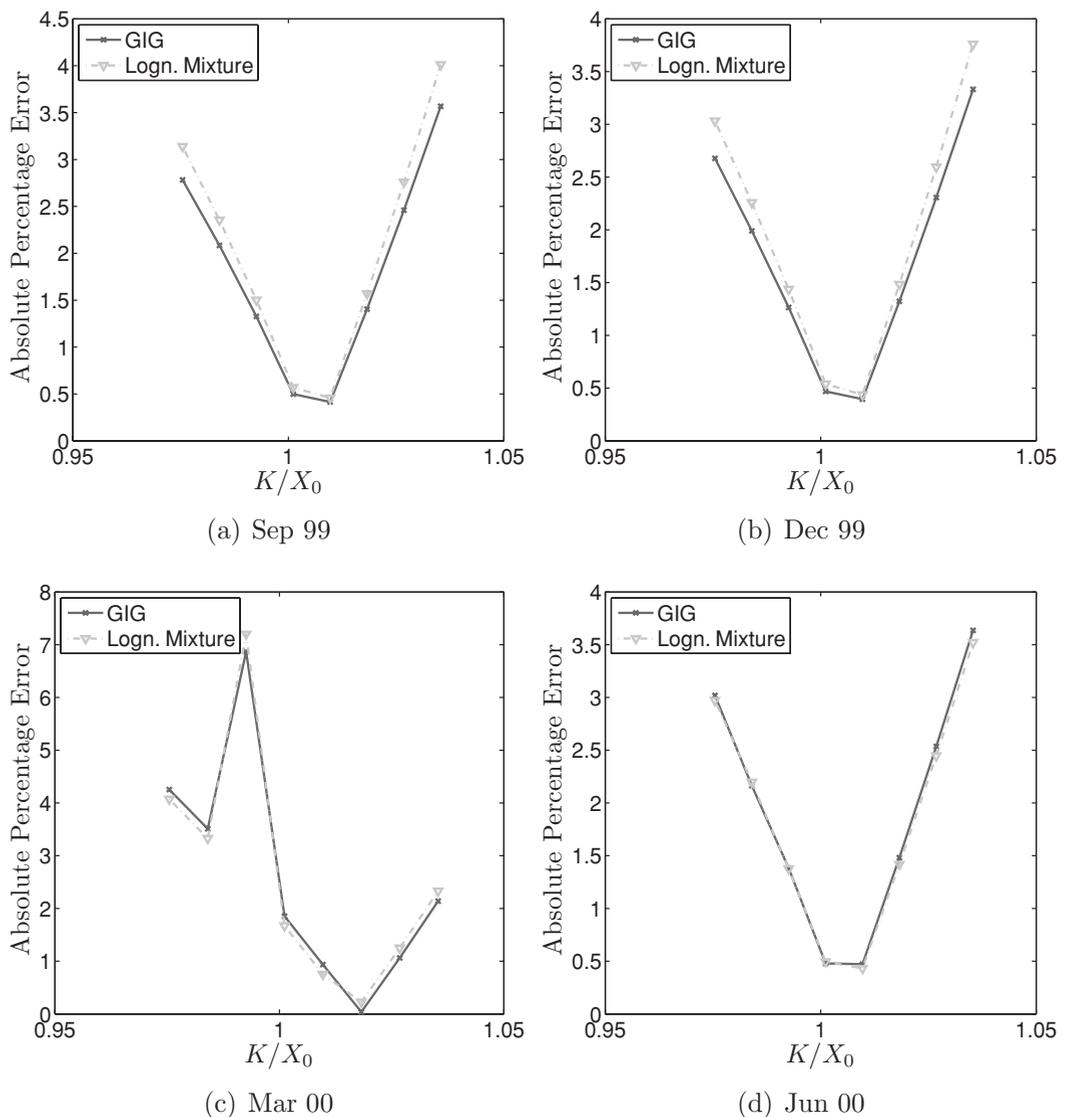

Figure 2 Absolute Percentage Errors for the Last Four Maturities

components K_j/X_0 reflecting moneyness. The smaller the value, the better is the fit. It is interesting that the GIG distribution, having three parameters, seems to calibrate across maturities very closely and is even a superior fit than the lognormal mixture (LnMix) model that uses five parameters.

A more informative comparison can be done by looking at the error structure versus moneyness. The fitting error for the two models and for each maturity are plotted in Figures 1 and 2 as the absolute percentage errors, defined for the European call option prices as $100 \times |C(\hat{\theta}; \mathbf{m}) - C^{mkt}(\mathbf{m})|/C^{mkt}(\mathbf{m})$, where $C(\hat{\theta}; \mathbf{m})$ is the same as the theoretical prices established in equation (1), which is calculated for the estimated parameter vector $\hat{\theta}$ following the minimization procedure focused on the function given in (4). In the neighborhood of at-the-money prices, the absolute percentage error is less than 1%, while out-of-the-money or in-the-money, it may go even higher.

Which parametric model to use depends on the task at hand. It is possible that some parametric models perform better for some asset classes (such as foreign exchange), while other models perform better for different asset classes (such as equity). Some models may have a superior fit in the tails.

KEY POINTS

- The information contained in the risk-neutral density is useful to many participants in financial markets. Central banks use this information in monitoring the stability of the financial system and for assessing the impact of new policies, and banks use it for marking positions in exotic derivatives that they hold.
- To recover the RND, a bundle of market prices for European vanilla call and put options on the same underlying asset and with the same maturity is used.
- Parametric and nonparametric models have been proposed for estimating the RND. For

several reasons, in practice, parametric models are better to employ. The main elements of a parametric model to estimate RND are an option pricing formula combined with a forward price formula, a minimization procedure, and a database of observed option prices.

- RND estimation can be done easily with parametric models for which pricing formulas are available for European vanilla options. The generalized inverse Gaussian model and the lognormal mixture model are examples of such models.
- The calibration is done by minimizing a discrepancy measure between the theoretical model prices and the observed option market prices.

NOTE

1. $I_A(x)$ is the indicator function being equal to 1 when $x \in A$ and zero otherwise.

Financial Statement Analysis

Financial Statements

PAMELA P. DRAKE, PhD, CFA

J. Gray Ferguson Professor of Finance, College of Business, James Madison University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Much of the financial data that is used in financial modeling is drawn from the company's financial statements. The four basic financial statements are the balance sheet, the income statement, the statement of cash flows, and the statement of shareholders' equity. It is important to understand these data so that the information conveyed by them is interpreted properly in financial modeling. The financial statements are created using several assumptions that affect how to use and interpret the financial data.

Financial statements are summaries of the operating, financing, and investment activities of a business. Financial statements should provide information useful to both investors and creditors in making credit, investment, and other business decisions. And this usefulness means that investors and creditors can use these statements to predict, compare, and evaluate the amount, timing, and uncertainty of future cash flows.¹ In other words, *financial statements* provide the information needed to assess a company's future earnings and, therefore, the cash flows expected to result from those earnings.

Information from financial statements is typically used in financial modeling for forecasting and valuation purposes. In this entry, we discuss the general principles that guide the preparation of financial statements (generally

accepted accounting principles), the four basic financial statements (balance sheet, income statement, statement of cash flows, and statement of shareholders' equity), and the assumptions underlying the preparation of financial statements.

ACCOUNTING PRINCIPLES

The accounting data in financial statements are prepared by the firm's management according to a set of standards, referred to as *generally accepted accounting principles* (GAAP). Generally accepted accounting principles consist of the FASB Accounting Standards Codification, and, for publicly-traded companies, the rules and releases of the Securities and Exchange Commission.²

The financial statements of a company whose stock is publicly traded must, by law, be audited at least annually by independent public accountants (i.e., accountants who are not employees of the firm). In such an audit, the accountants examine the financial statements and the data from which these statements are prepared and attest—through the published auditor’s opinion—that these statements have been prepared according to GAAP. The auditor’s opinion focuses on whether the statements conform to GAAP and that there is adequate disclosure of any material change in accounting principles.

The financial statements are created using several assumptions that affect how we use and interpret the financial data:

- *Transactions are recorded at historical cost.* Therefore, the values shown in the statements are not market or replacement values, but rather reflect the original cost (adjusted for depreciation in the case of depreciable assets).
- *The appropriate unit of measurement is the dollar.* While this seems logical, the effects of inflation, combined with the practice of recording values at historical cost, may cause problems in using and interpreting these values.
- *The statements are recorded for predefined periods of time.* Generally, statements are produced to cover a chosen fiscal year or quarter, with the income statement and the statement of cash flows spanning a period’s time and the balance sheet and statement of shareholders’ equity as of the end of the specified period. But because the end of the fiscal year is generally chosen to coincide with the low point of activity in the operating cycle, the annual balance sheet and statement of shareholders’ equity may not be representative of values for the year.
- *Statements are prepared using accrual accounting and the matching principle.* Most businesses use accrual accounting, where income and revenues are matched in timing such that income is recorded in the period in which it is earned and expenses are reported in the period in which they are incurred in an attempt to generate revenues. The result of the use of accrual accounting is that reported income does not necessarily coincide with cash flows. Because the financial analyst is concerned ultimately with cash flows, he or she often must understand how reported income relates to a company’s cash flows.
- *It is assumed that the business will continue as a going concern.* The assumption that the business enterprise will continue indefinitely justifies the appropriateness of using historical costs instead of current market values because these assets are expected to be used up over time instead of sold.
- *Full disclosure requires providing information beyond the financial statements.* The requirement that there be full disclosure means that, in addition to the accounting numbers for such accounting items as revenues, expenses, and assets, narrative and additional numerical disclosures are provided in notes accompanying the financial statements. An analysis of financial statements is, therefore, not complete without this additional information.
- *Statements are prepared assuming conservatism.* In cases in which more than one interpretation of an event is possible, statements are prepared using the most conservative interpretation.

The financial statements and the auditors’ findings are published in the firm’s annual and quarterly reports sent to shareholders and the 10-K and 10-Q filings with the Securities and Exchange Commission (SEC). Also included in the reports, among other items, is a discussion by management, providing an overview of company events. The annual reports are much more detailed and disclose more financial information than the quarterly reports.

INFORMATION CONVEYED BY THE BASIC FINANCIAL STATEMENTS

In this section we will discuss the four basic financial statements and the information that they convey.

The Balance Sheet

The *balance sheet* is a report of the assets, liabilities, and equity of a firm at a point in time, generally at the end of a fiscal quarter or fiscal year. *Assets* are resources of the business enterprise, which are comprised of current or long-lived assets. How did the company finance these resources? It did so with liabilities and equity. *Liabilities* are obligations of the business enterprise that must be repaid at a future point in time, whereas equity is the ownership interest of the business enterprise. The relation between assets, liabilities and equity is simple, as reflected in the balance of what is owned and how it is financed, referred to as the accounting identity:

$$\text{Assets} = \text{Liabilities} + \text{Equity}$$

Assets

Assets are anything that the company owns that has a value. These assets may have a physical existence or not. Examples of physical assets include inventory items held for sale, office furniture, and production equipment. If an asset does not have a physical existence, we refer to it as an intangible asset, such as a trademark or a patent. You cannot see or touch an intangible asset, but it still contributes value to the company.

Assets may also be current or long-term, depending on how fast the company would be able to convert them into cash. Assets are generally reported in the balance sheet in order of liquidity, with the most liquid asset listed first and the least liquid listed last.

The most liquid assets of the company are the current assets. Current assets are assets that can be turned into cash in one operating cycle or one year, whichever is longer. This contrasts with the noncurrent assets, which cannot be liquidated quickly.

There are different types of current assets. The typical set of current assets is the following:

- Cash, bills, and currency are assets that are equivalent to cash (e.g., bank account).
- Marketable securities, which are securities that can be readily sold.
- Accounts receivable, which are amounts due from customers arising from trade credit.
- Inventories, which are investments in raw materials, work-in-process, and finished goods for sale.

A company's need for current assets is dictated, in part, by its operating cycle. The operating cycle is the length of time it takes to turn the investment of cash into goods and services for sale back into cash in the form of collections from customers. The longer the operating cycle, the greater a company's need for liquidity. Most firms' operating cycle is less than or equal to one year.

Noncurrent assets comprise both physical and nonphysical assets. Plant assets are physical assets, such as buildings and equipment, and are reflected in the balance sheet as gross plant and equipment and net plant and equipment. Gross plant and equipment, or gross property, plant, and equipment, is the total cost of investment in physical assets; that is, what the company originally paid for the property, plant, and equipment that it currently owns. Net plant and equipment, or net property, plant, and equipment, is the difference between gross plant and equipment and accumulated depreciation, and represents the book value of the plant and equipment assets. Accumulated depreciation is the sum of depreciation taken for

physical assets in the firm's possession. Therefore,

$$\begin{aligned} & \text{Gross plant and equipment} \\ & - \text{Accumulated depreciation} \\ \hline & = \text{Net plant and equipment} \end{aligned}$$

Companies may present just the net plant and equipment figure on the balance sheet, placing the detail with respect to accumulated depreciation in a footnote. Interpreting financial statements requires knowing a bit about how assets are depreciated for financial reporting purposes. Depreciation is the allocation of the cost of an asset over its useful life (or economic life). In the case of the fictitious Sample Company, whose balance sheet is shown in Table 1, the

original cost of the fixed assets (i.e., plant, property, and equipment)—less any write-downs for impairment—for year 2 is \$900 million. The accumulated depreciation for Sample in Year 1 is \$250 million; this means that the total depreciation taken on existing fixed assets over time is \$270 million. The net property, plant, and equipment account balance is \$630 million. This is also referred to as the book value or carrying value of these assets.

Intangible assets are assets that are not financial instruments, yet have no physical existence, such as patents, trademarks, copyrights, franchises, and formulas. Intangible assets may be amortized over some period, which is akin to depreciation. Keep in mind that a company may own a number of intangible assets that are not reported on the balance sheet. A company may only include an intangible asset's value on its balance sheet if (1) there are likely future benefits attributable specifically to the asset, and (2) the cost of the intangible asset can be measured.

Suppose a company has an active, ongoing investment in research and development to develop new products. It must expense what is spent on research and development each year because a given investment in R&D does not likely meet the two criteria because it is not until much later, after the R&D expense is made, that the economic viability of the investment is determined. If, on the other hand, a company buys a patent from another company, this cost may be capitalized and then amortized over the remaining life of the patent. So when you look at a company's assets on its balance sheet, you may not be getting the complete picture of what it owns.

Liabilities

We generally use the terms "liability" and "debt" as synonymous terms, though "liability" is actually a broader term, encompassing not only the explicit contracts that a company has, in terms of short-term and long-term debt obligations, but also obligations that are not specified in a contract, such as environmental

Table 1 The Sample Company Balance Sheet for Years 1 and 2 (in millions)

	Year 2	Year 1
Cash	\$40	\$30
Accounts receivable	100	90
Inventory	180	200
Other current assets	10	10
TOTAL CURRENT ASSETS	\$350	\$330
Property, plant, and equipment	\$900	\$800
Less accumulated depreciation	270	200
Net property, plant, and equipment	630	600
Intangible assets	20	20
TOTAL ASSETS	\$1,000	\$950
Accounts payable	\$150	\$140
Current maturities of long-term debt	60	40
TOTAL CURRENT LIABILITIES	\$180	\$165
Long-term debt	300	250
TOTAL LIABILITIES	\$380	\$325
Minority interest	30	15
Common stock	50	50
Additional paid-in capital	100	100
Retained earnings	500	400
TOTAL SHAREHOLDERS' EQUITY	650	550
TOTAL LIABILITIES AND SHAREHOLDERS' EQUITY	\$1,000	\$950

obligations or asset retirement obligations. Liabilities may be interest-bearing, such as a bond issue, or noninterest-bearing, such as amounts due to suppliers.

In the balance sheet, liabilities are presented in order of their due date and are often presented in two categories, current liabilities and long-term liabilities. Current liabilities are obligations due within one year or one operating cycle (whichever is longer). Current liabilities consist of:

- Accounts payable are amounts due to suppliers for purchases on credit.
- Wages and salaries payable are amounts due employees.
- Current portion of long-term indebtedness.
- Short-term bank loans.

Long-term liabilities are obligations that are due beyond one year. There are different types of long-term liabilities, including:

- Notes payables and bonds, which are indebtedness (loans) in the form of securities
- Capital leases, which are rental obligations that are long-term, fixed commitments
- Asset retirement liability, which is the contractual or statutory obligation to retire or decommission the asset and restore the site to required standards at the end of the asset's life
- Deferred taxes, which are taxes that may have to be paid in the future that are currently not due, though they are expensed for financial reporting purposes. Deferred taxes arise from differences between accounting and tax methods (e.g., depreciation methods).

Note that although deferred income taxes are often referred to as liabilities, some analysts will classify them as equity if the deferral is perceived to be perpetual. For example, a company that buys new depreciable assets each year will always have some level of deferred taxes; in

that case, an analyst will classify deferred taxes as equity.

Equity

The equity of a company is the ownership interest. The book value of equity, which for a corporation is often referred to as shareholders' equity or stockholders' equity, is basically the amount that investors paid the company for their ownership interest, plus any earnings (or less any losses), and minus any distributions to owners. For a corporation, equity is the amount that investors paid the corporation for the stock when it was initially sold, plus or minus any earnings or losses, less any dividends paid. Keep in mind that for any company, the reported amount of equity is an accumulation over time since the company's inception (or incorporation, in the case of a corporation).

Shareholders' equity is the carrying or book value of the ownership of a company. Shareholders' equity comprises:

+ Par value	A nominal amount per share of stock (sometimes prescribed by law), or the stated value, which is a nominal amount per share of stock assigned for accounting purposes if the stock has no par value.
+ Additional paid-in-capital	Also referred to as capital surplus, the amount paid for shares of stock by investors in excess of par or stated value.
– Treasury stock	The accounting value of shares of the firm's own stock bought by the firm.
+ Retained earnings	The accumulation of prior and current periods' earnings and losses, less any prior or current periods' dividends.
± Accumulated comprehensive income or loss	The total amount of income or loss that arises from transactions that result in income or losses, yet are not reported through the income statement. Items giving rise to this income include foreign currency translation adjustments and unrealized gains or losses on available-for-sale investments.

= Shareholders' equity

A Note on Minority Interest

On many companies' consolidated financial statements, you will notice a balance sheet account titled *Minority Interest*. When a company owns a substantial portion of another company, the accounting principles require that the company consolidate that company's financial statements into its own. Basically what happens in consolidating the financial statements is that the parent company will add the accounts of the subsidiary to its accounts (i.e., subsidiary inventory + parent inventory = consolidated inventory).³ If the parent does not own 100% of the subsidiary's ownership interest, an account is created, referred to as minority interest, which reflects the amount of the subsidiary's assets not owned by the parent. This account will be presented between liabilities and equity on the consolidated balance sheet. Is it a liability or an equity account? It is neither.

A similar adjustment takes place on the income statement. The minority interest account on the income statement reflects the income (or loss) in proportion to the equity in the subsidiary not owned by the parent.

Structure of the Balance Sheet

Consider a simple balance sheet for the Sample Company shown in Table 1 for fiscal years Year 1 and Year 2. The most recent fiscal year's data is presented in the left-most column of data. Notice that the accounting identity holds; that is, total assets are equal to the sum of the total liabilities and the total shareholders' equity.

The Income Statement

The *income statement* is a summary of operating performance over a period of time (e.g., a fiscal quarter or a fiscal year). We start with the revenue of the company over a period of time and then subtract the costs and expenses related to that revenue. The bottom line of the income statement consists of the owners' earnings for the period. To arrive at this "bottom line," we need to compare revenues and expenses. The

basic structure of the income statement includes the following:

Sales or revenues	⇐ Represent the amount of goods or services sold, in terms of price paid by customers
Less: Cost of goods sold (or cost of sales)	⇐ The amount of goods or services sold, in terms of cost to the firm
Gross profit	⇐ The difference between sales and cost of goods sold
Less: Selling and general expenditures	⇐ Salaries, administrative, marketing expenditures, etc.
Operating profit	⇐ Income from operations (ignores effects of financing decisions and taxes); earnings before interest and taxes (EBIT), operating income, and operating earnings
Less: Interest expense	⇐ Interest paid on debt
Net income before taxes	⇐ Earnings before taxes
Less: Taxes	⇐ Taxes expense for the current period
Net income	⇐ Operating profit less financing expenses (e.g., interest) and taxes
Less: Preferred stock dividends	⇐ Dividends paid to preferred shareholders
Earnings available to common shareholders	⇐ Net income less preferred stock dividends; residual income

Though the structure of the income statement varies by company, the basic idea is to present the operating results first, followed by non-operating results. The cost of sales, also referred to as the cost of goods sold, is deducted from revenues, producing a gross profit; that is, a profit without considering all other, general operating costs. These general operating expenses are those expenses related to the support of the general operations of the company, which includes salaries, marketing costs, and research and development. Depreciation, which is the amortized cost of physical assets, is also deducted from gross profit. The amount of the depreciation expense represents the cost of the wear and tear on the property, plant, and equipment of the company.

Table 2 The Sample Company Income Statement for Year 2 (in millions)

Sales	\$1,000
Cost of goods sold	600
Gross profit	\$400
Depreciation	50
Selling, general, and administrative expenses	160
Operating profit	\$190
Interest expense	23
Income before taxes	\$167
Taxes	67
Net income	\$100

Once we have the operating income, we have summarized the company's performance with respect to the operations of the business. But there is generally more to a company's performance. From operating income, we deduct interest expense and add any interest income. Further, adjustments are made for any other income or cost that is not a part of the company's core business.

There are a number of other items that may appear as adjustments to arrive at net income. One of these is extraordinary items, which are defined as unusual and infrequent gains or losses. Another adjustment would be for the expense related to the write-down of an asset's value.

In the case of the Sample Company, whose income statement is presented in Table 2, the income from operations—its core business—is \$190 million, whereas the net income (i.e., the "bottom line") is \$100 million.

Earnings Per Share

Companies provide information on *earnings per share* (EPS) in their annual and quarterly financial statement information, as well as in their periodic press releases. Generally, EPS is calculated as net income, divided by the number of shares outstanding. Companies must report both basic and diluted earnings per share.

Basic earnings per share is net income (minus preferred dividends), divided by the average number of shares outstanding. Diluted earnings

per share is net income (minus preferred dividends), divided by the number of shares outstanding considering all dilutive securities (e.g., convertible debt, options). Diluted earnings per share, therefore, gives the shareholder information about the potential dilution of earnings. For companies with a large number of dilutive securities (e.g., stock options, convertible preferred stock or convertible bonds), there can be a significant difference between basic and diluted EPS. You can see the effect of dilution by comparing the basic and diluted EPS.

More on Depreciation

There are different methods that can be used to allocate an asset's cost over its life. Generally, if the asset is expected to have value at the end of its economic life, the expected value, referred to as a salvage value (or residual value), is not depreciated; rather, the asset is depreciated down to its salvage value. There are different methods of depreciation that we classify as either straight-line or accelerated. Straight-line depreciation allocates the cost (less salvage value) in a uniform manner (equal amount per period) throughout the asset's life. Accelerated depreciation allocates the asset's cost (less salvage value) such that more depreciation is taken in the earlier years of the asset's life. There are alternative accelerated methods available, including:

- Declining balance method, in which a constant rate is applied to a declining amount (the undepreciated cost)
- Sum-of-the-years' digits method, in which a declining rate is applied to the asset's depreciable basis

Another method is the units-of-activity method, in which the useful life is defined in terms of a measure of units of production or some other metric or use (e.g., hours, miles). The depreciation expense in any period is determined as the usage in that period.

A common declining balance method is the double-declining balance method (DDB), which applies the rate that is twice that of the straight-line rate. In this case, the straight-line rate is 10% per year; therefore, the declining balance rate is 20% per year. We apply this rate of 20% against the original cost of \$1,000,000, resulting in a depreciation expense in the first year of \$200,000. In the second year, we apply this 20% against the undepreciated balance of $\$1,000,000 - 200,000 = \$800,000$, resulting in a depreciation of \$160,000.

Because the declining balance methods result in more depreciation sooner, relative to straight-line, and lower depreciation in the later years, companies may switch to straight-line in these later years. The same amount is depreciated over the life of the asset, but the pattern—and depreciation's impact on earnings—is modified slightly. In the case of the declining balance method, salvage value is not considered in the calculation of depreciation until the undepreciated balance reaches the salvage value.

For this same asset, the sum-of-the-years' digits (SYD) depreciation for the first year is the rate of $10/55$, or 18.18%, applied against the depreciable basis of $\$1,000,000 - 100,000 = \$900,000$:

$$\text{SYD first year} = \$900,000(10/55) = \$163,636$$

We calculate the denominator as the "sum of the years": $10 + 9 + 8 + 7 + 6 + 5 + 4 + 3 + 2 + 1 = 55$. In the second year, the rate is $9/55$ applied against the \$900,000, and so on.

Accelerated methods result in higher depreciation expenses in earlier years, relative to straight-line, as can be seen in Figure 1. As a result, accelerated methods result in lower reported earnings in earlier years, relative to straight-line. When comparing companies, it is important to understand whether the companies use different methods of depreciation because the choice of depreciation method affects both the balance sheet (through the carrying value of the asset) and the income statement (through the depreciation expense).

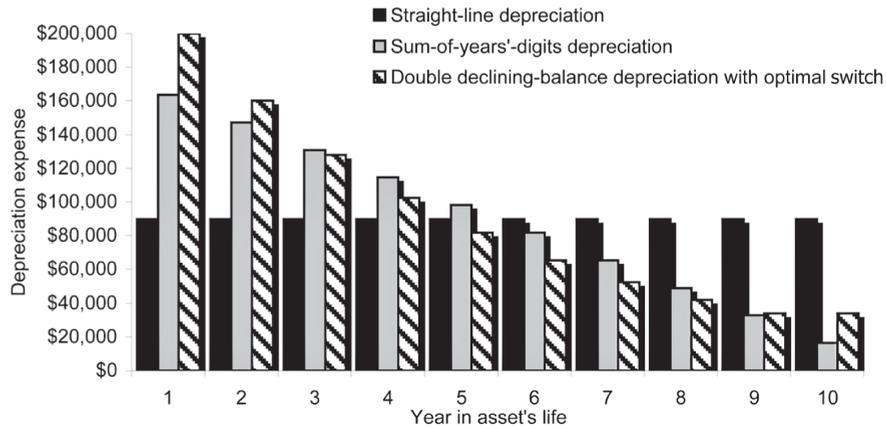

A major source of deferred income taxes and deferred tax assets is the accounting methods used for financial reporting purposes and tax purposes. In the case of financial accounting purposes, the company chooses the method that best reflects how its assets lose value over time, though most companies use the straight-line method. However, for tax purposes the company has no choice but to use the prescribed rates of depreciation, using the Modified Accelerated Cost Recovery System (MACRS). For tax purposes, a company does not have discretion over the asset's depreciable life or the rate of depreciation—they must use the MACRS system.

The MACRS system does not incorporate salvage value and is based on a declining balance system. The depreciable life for tax purposes may be longer than or shorter than that used for financial reporting purposes. For example, the MACRS rate for 3- and 5-year assets are as follows:

Year	3-year	5-year
1	33.33%	20.00%
2	44.45%	32.00%
3	14.81%	19.20%
4	7.41%	11.52%
5		11.52%
6		5.76%

You'll notice the fact that a 3-year asset is depreciated over four years and a 5-year asset is depreciated over six years. That is the result of using what is referred to as a half-year convention—using only half a year's worth of depreciation in the first year of an asset's life. This system results in a leftover amount that must still be depreciated in the last year (i.e., the fourth year in the case of a 3-year asset and the sixth year in the case of a 5-year asset). We provide a comparison of straight-line and MACRS depreciation in Figure 2. You can see that the methods produce different depreciation expenses, which result in the different income amounts for tax and financial reporting purposes.

Panel A: Depreciation Expense

Panel B: Book Value of the Asset

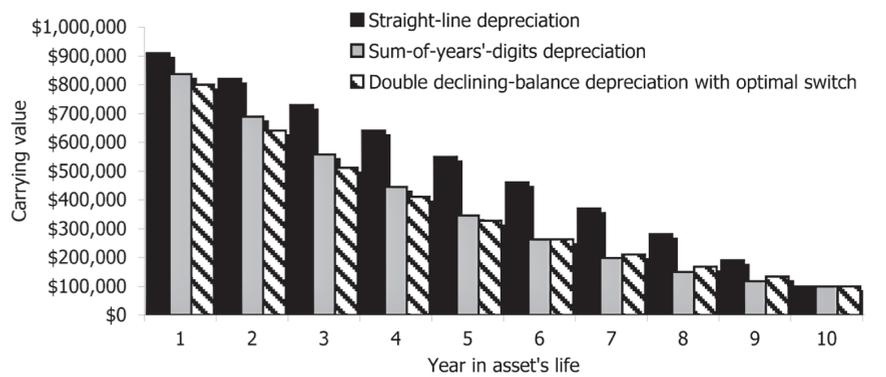

Figure 1 Comparison of Depreciation Expense and Book Value
 Depreciation expense each year for an asset with an original cost of \$1,000,000, a salvage value of \$10,000, and a 10-year useful life

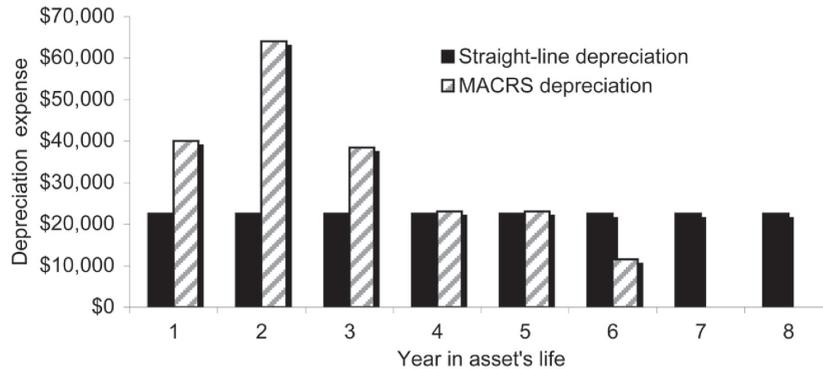

The Statement of Cash Flows

The *statement of cash flows* is the summary of a firm’s cash flows, summarized by operations, investment activities, and financing activities. A simplified cash flow statement is provided in Table 3 for the fictitious Sample Company. Cash flow from operations is cash flow from day-to-day operations. Cash flow from operating activities is basically net income adjusted for (1) noncash expenditures, and (2) changes in working capital accounts. The adjustment for

changes in working capital accounts is necessary to adjust net income that is determined using the accrual method to a cash flow amount. Increases in current assets and decreases in current liabilities are positive adjustments to arrive at the cash flow; decreases in current assets and increases in current liabilities are negative adjustments to arrive at the cash flow.

Cash flow for/from investing is the cash flows related to the acquisition (purchase) of plant, equipment, and other assets, as well as the

Panel A: Depreciation Expense

Panel B: Carrying Value

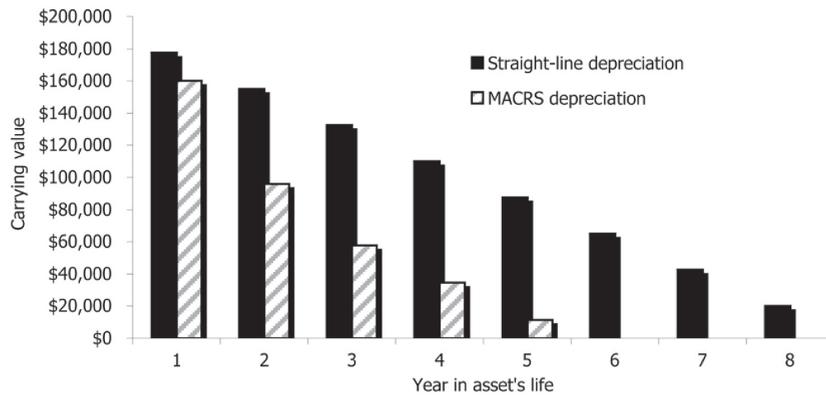

Figure 2 Depreciation for Financial Accounting Purposes versus Tax Purposes

Consider an asset that costs \$200,000 and has a salvage value of \$20,000. If the asset has a useful life of 8 years, but is classified as a 5-year asset for tax purposes, the depreciation and book value of the asset will be different between the financial accounting records and the tax records

proceeds from the sale of assets. Cash flow for/ from financing activities is the cash flow from activities related to the sources of capital funds (e.g., buy back common stock, pay dividends, issue bonds).

Not all of the classifications required by accounting principles are consistent with the true flow for the three types of activities. For example, interest expense is a financing cash flow, yet it affects the cash flow from operating activities because it is a deduction to arrive at net income. This inconsistency is also the case for interest

income and dividend income, both of which result from investing activities, but show up in the cash flow from operating activities through their contribution to net income.

The sources of a company's cash flows can reveal a great deal about the company and its prospects. For example, a financially healthy company tends to consistently generate cash flows from operations (that is, positive operating cash flows) and invests cash flows (that is, negative investing cash flows). To remain viable, a company must be able to generate funds

Table 3 The Sample Company Statement of Cash Flows, for the period ending December 31, 2006 (in millions)

Net income	\$100	
Add depreciation	50	
Subtract increase in accounts receivable	-10	
Add decrease in inventory	20	
Add increase in accounts payable	50	
Cash flow from operations		\$210
Retire debt	-\$100	
Cash flow for financing		-100
Purchase of equipment	-\$100	
Cash flow for investment		-100
Change in cash flow		\$10

from its operations; to grow, a company must continually make capital investments.

The change in cash flow—also called net cash flow—is the bottom line in the statement of cash flows and is equal to the change in the cash account as reported on the balance sheet. For the Sample Company, shown in Table 3, the net change in cash flow is a positive \$10 million; this is equal to the change in the cash account from \$50 million in Year 1 to \$60 million in Year 2.

By studying the cash flows of a company over time, we can gauge a company's financial health. For example, if a company relies on external financing to support its operations (that is, reliant on cash flows from financing and not from operations) for an extended period of time, this is a warning sign of financial trouble up ahead.

The Statement of Stockholders' Equity

The *statement of stockholders' equity* (also referred to as the *statement of shareholders' equity*) is a summary of the changes in the equity accounts, including information on stock options exercised, repurchases of shares, and Treasury shares. The basic structure is to include a reconciliation of the balance in each component of equity from the beginning of the fiscal year with the end of the fiscal year, detailing changes

attributed to net income, dividends, purchases or sales of Treasury stock. The components are common stock, additional paid-in capital, retained earnings, and Treasury stock. For each of these components, the statement begins with the balance of each at the end of the previous fiscal period and then adjustments are shown to produce the balance at the end of the current fiscal period.

In addition, there is a reconciliation of any gains or losses that affect stockholders' equity but which do not flow through the income statement, such as foreign-currency translation adjustments and unrealized gains on investments. These items are of interest because they are part of comprehensive income, and hence income to owners, but they are not represented on the company's income statement.

Why Bother About the Footnotes?

Footnotes to the financial statements contain additional information, supplementing or explaining financial statement data. These notes are presented in both the annual report and the 10-K filing (with the SEC), though the latter usually provides a greater depth of information.

The footnotes to the financial statements provide information pertaining to:

- *The significant accounting policies and practices that the company uses.* This helps the analyst with the interpretation of the results, comparability of the results to other companies and to other years for the same company, and in assessing the quality of the reported information.
- *Income taxes.* The footnotes tell us about the company's current and deferred income taxes, breakdowns by the type of tax (e.g., federal versus state), and the effective tax rate that the company is paying.
- *Pension plans.* The detail about pension plans, including the pension assets and the pension liability, is important in determining whether a company's pension plan is overfunded or underfunded.

- *Leases*. You can learn about both the capital leases, which are the long-term lease obligations that are reported on the balance sheet, and about the future commitments under operating leases, which are not reflected on the balance sheet.
- *Long-term debt*. You can find detailed information about the maturity dates and interest rates on the company's debt obligations.

The phrase “the devil is in the details” applies aptly to the footnotes of a company's financial statement. Through the footnotes, a company is providing information that is crucial in analyzing a company's financial health and performance. If footnotes are vague or confusing, as they were in the case of Enron prior to the break in the scandal, the analyst must ask questions to help understand this information.

ACCOUNTING FLEXIBILITY

The generally accepted accounting principles provide some choices in the manner in which some transactions and assets are accounted. For example, a company may choose to account for inventory, and hence costs of sales, using Last-in, First-out (LIFO) or First-in, First-out (FIFO). This is intentional because these principles are applied to a broad set of companies and no single set of methods offers the best representation of a company's condition or performance for all companies. Ideally, a company's management, in consultation with the accountants, chooses those accounting methods and presentations that are most appropriate for the company.

A company's management has always had the ability to manage earnings through the judicious choice of accounting methods within the GAAP framework. The company's “watchdogs” (i.e., the accountants) should keep the company's management in check. However, recent scandals have revealed that the watchdog function of the accounting firms was not working well. Additionally, some companies'

management used manipulation of financial results and outright fraud to distort the financial picture.

The Sarbanes-Oxley Act of 2002 offers some comfort in terms of creating the oversight board for the auditing accounting firms. In addition, the Securities and Exchange Commission, the Financial Accounting Standards Board, and the International Accounting Standards Board are tightening some of the flexibility that companies had in the past.

Pro Forma Financial Data

Pro forma financial information is really a misnomer—the information is neither pro forma (that is, forward looking), nor reliable financial data. What is it? Creative accounting. It started during the Internet-tech boom in the 1990s and persists today: Companies release financial information that is prepared according to its own liking, using accounting methods that they create.

Why did companies start doing this? What is wrong with generally accepted accounting principles (GAAP)? During the Internet-tech stock boom, many startup companies quickly went public and then felt the pressures to generate profits. However, profits in that industry were hard to come by during that period of time. What some companies did is generate financial data that they included in company releases that reported earnings not calculated using GAAP—but rather by methods of their own. In some cases, these alternative methods hid a lot of the ills of these companies.

The use of pro forma financial data may be helpful, but also may be misleading to investors. Analysts routinely adjust published financial statement data to remove unusual, nonrecurring items. This can give the analyst a better predictor of the continued performance of the company. So what is wrong with the company itself doing this? Nothing, unless it becomes misleading, such as a company including its nonrecurring gains, but not including its

nonrecurring losses. In concern for the possibility of misleading information being given to investors, the Securities and Exchange Commission now requires that if companies release pro forma financial data, they must also reconcile this data with GAAP.⁴

KEY POINTS

- There are four basic financial statements: the balance sheet, the income statement, the statement of cash flows, and the statement of stockholders' equity.
 - The balance sheet and the statement of shareholders' equity are statements with values of accounts at a point in time. In the case of the balance sheet, the company presents data as of the end of the most recent two years; in the case of the statement of shareholders' equity, from the latest fiscal year to the end. The income statement and the statement of cash flows provide data on earnings and cash flows over the period, whether that period is a fiscal quarter or year.
 - The information conveyed in the footnotes is essential to the understanding of financial statements. There is detail in these footnotes that gives us a better idea of the financial health of the company. The financial statements and the accompanying footnotes provide the accounting principles that guide companies in the preparation of financial statements.
- Not only must the accounting methods that a company uses be understood, but the choices that a company has made among the available accounting methods should be understood.

NOTES

1. The purpose, focus, and objectives of financial statements are detailed in Financial Accounting Standards Board (1978, 1980).
2. Effective July 1, 2009, Financial Accounting Standards Board (FASB) Accounting Standards Codification.
3. There are other adjustments made for intercorporate transactions, but we will not go into these in this entry.
4. Securities and Exchange Commission RIN3235-A169, "Conditions for Use of Non-GAAP Financial Measures," effective March 28, 2003.

Financial Ratio Analysis

PAMELA P. DRAKE, PhD, CFA

J. Gray Ferguson Professor of Finance, College of Business, James Madison University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Financial analysis involves the selection, evaluation, and interpretation of financial data and other pertinent information to assist in evaluating the operating performance and financial condition of a company. The operating performance of a company is a measure of how well a company has used its resources—its assets, both tangible and intangible—to produce a return on its investment. The financial condition of a company is a measure of its ability to satisfy its obligations, such as the payment of interest on its debt in a timely manner. The analyst has many tools available in the analysis of financial information. These tools include financial ratio analysis and quantitative analysis. The analyst must understand how to use these tools, along with economics and accounting information, in the most effective manner.

Financial analysis is one of the many tools useful in valuation because it helps analysts and investors gauge returns and risks. In this entry, we explain and illustrate financial ratios—one of the tools of financial analysis. In financial ratio analysis we select the relevant information—primarily the financial statement data—and evaluate it. We show how to incorporate market data and economic data in the analysis of financial ratios. Finally, we show how to interpret financial ratio analysis, identifying the pitfalls that occur when it's not done properly.

RATIOS AND THEIR CLASSIFICATION

A ratio is a mathematical relation between two quantities. Suppose you have 200 apples and

100 oranges. The ratio of apples to oranges is $200/100$, which we can conveniently express as 2:1 or 2. A financial ratio is a comparison between one bit of financial information and another. Consider the ratio of current assets to current liabilities, which we refer to as the current ratio. This ratio is a comparison between assets that can be readily turned into cash—current assets—and the obligations that are due in the near future—current liabilities. A current ratio of 2 or 2:1 means that we have twice as much in current assets as we need to satisfy obligations due in the near future.

Ratios can be classified according to the way they are constructed and the financial characteristic they are describing. For example, we will see that the current ratio is constructed as a coverage ratio (the ratio of current

assets—available funds—to current liabilities—the obligation) that we use to describe a firm's liquidity (its ability to meet its immediate needs).

There are as many different *financial ratios* as there are possible combinations of items appearing on the income statement, balance sheet, and statement of cash flows. We can classify ratios according to how they are constructed or according to the financial characteristic that they capture.

Ratios can be constructed in the following four ways:

1. As a *coverage ratio*. A coverage ratio is a measure of a firm's ability to "cover," or meet, a particular financial obligation. The denominator may be any obligation, such as interest or rent, and the numerator is the amount of the funds available to satisfy that obligation.
2. As a *return ratio*. A return ratio indicates a net benefit received from a particular investment of resources. The net benefit is what is left over after expenses, such as operating earnings or net income, and the resources may be total assets, fixed assets, inventory, or any other investment.
3. As a *turnover ratio*. A turnover ratio is a measure of how much a firm gets out of its assets. This ratio compares the gross benefit from an activity or investment with the resources employed in it.
4. As a *component percentage*. A component percentage is the ratio of one amount in a financial statement, such as sales, to the total of amounts in that financial statement, such as net profit.

In addition, we can also express financial data in terms of time—say, how many days' worth of inventory we have on hand—or on a per-share basis—say, how much a firm has earned for each share of common stock. Both are measures we can use to evaluate operating performance or financial condition.

When we assess a firm's operating performance, a concern is whether the company is

applying its assets in an efficient and profitable manner. When an analyst assesses a firm's financial condition, a concern is whether the company is able to meet its financial obligations. The analyst can use financial ratios to evaluate five aspects of operating performance and financial condition:

1. Return on investment
2. Liquidity
3. Profitability
4. Activity
5. Financial leverage

There are several ratios reflecting each of the five aspects of a firm's operating performance and financial condition. We apply these ratios to the Fictitious Corporation, whose balance sheets, income statements, and statement of cash flows for two years are shown in Tables 1, 2, and 3, respectively. We refer to the most recent fiscal year for which financial statements

Table 1 Fictitious Corporation Balance Sheets for Years Ending December 31, in Thousands

	Current Year	Prior Year
ASSETS		
Cash	\$400	\$200
Marketable securities	200	0
Accounts receivable	600	800
Inventories	<u>1,800</u>	<u>1,000</u>
Total current assets	<u>\$3,000</u>	<u>\$2,000</u>
Gross plant and equipment	\$11,000	\$10,000
Accumulated depreciation	<u>(4,000)</u>	<u>(3,000)</u>
Net plant and equipment	7,000	7,000
Intangible assets	<u>1,000</u>	<u>1,000</u>
Total assets	<u>\$11,000</u>	<u>\$10,000</u>
LIABILITIES AND SHAREHOLDERS' EQUITY		
Accounts payable	\$500	\$400
Other current liabilities	500	200
Long-term debt	<u>4,000</u>	<u>5,000</u>
Total liabilities	<u>\$5,000</u>	<u>\$5,600</u>
Common stock, \$1 par value; Authorized 2,000,000 shares Issued 1,500,000 and 1,200,000 shares	1,500	1,200
Additional paid-in capital	1,500	800
Retained earnings	<u>3,000</u>	<u>2,400</u>
Total shareholders' equity	<u>6,000</u>	<u>4,400</u>
Total liabilities and shareholders' equity	<u>\$11,000</u>	<u>\$10,000</u>

Table 2 Fictitious Corporation Income Statements for Years Ending December 31, in Thousands

	Current Year	Prior Year
Sales	\$10,000	\$9,000
Cost of goods sold	(6,500)	(6,000)
Gross profit	\$3,500	\$3,000
Lease expense	(1,000)	(500)
Administrative expense	(500)	(500)
Earnings before interest and taxes (EBIT)	\$2,000	\$2,000
Interest	(400)	(500)
Earnings before taxes	\$1,600	\$1,500
Taxes	(400)	(500)
Net income	\$1,200	\$1,000
Preferred dividends	(100)	(100)
Earnings available to common shareholders	\$1,100	\$900
Common dividends	(500)	(400)
Retained earnings	\$600	\$500

are available as the “current year.” The “prior year” is the fiscal year prior to the current year.

The ratios we introduce here are by no means the only ones that can be formed using financial data, though they are some of the more commonly used. After becoming comfortable with the tools of financial analysis, an analyst will be able to create ratios that serve a particular evaluation objective.

RETURN-ON-INVESTMENT RATIOS

Return-on-investment ratios compare measures of benefits, such as earnings or net income, with measures of investment. For example, if an analyst wants to evaluate how well the firm uses its assets in its operations, he could calculate the *return on assets*—sometimes called the *basic earning power ratio*—as the ratio of earnings before interest and taxes (EBIT) (also known as *operating earnings*) to total assets:

$$\text{Basic earning power} = \frac{\text{Earnings before interest and taxes}}{\text{Total assets}}$$

Table 3 Fictitious Company Statement of Cash Flows, Years Ended December 31, in Thousands

	Current Year	Prior Year
Cash flow from (used for) operating activities		
Net income	\$1,200	\$1,000
Add or deduct adjustments to cash basis:		
Change in accounts receivables	\$200	\$(200)
Change in accounts payable	100	400
Change in marketable securities	(200)	200
Change in inventories	(800)	(600)
Change in other current liabilities	300	0
Depreciation	1,000	1,000
	<u>600</u>	<u>800</u>
Cash flow from operations	\$1,800	\$1,800
Cash flow from (used for) investing activities		
Purchase of plant and equipment	\$(1,000)	\$0
Cash flow from (used for) investing activities	\$(1,000)	\$0
Cash flow from (used for) financing activities		
Sale of common stock	\$1,000	\$0
Repayment of long-term debt	(1,000)	(1,500)
Payment of preferred dividends	(100)	(100)
Payment of common dividends	(500)	(400)
Cash flow from (used for) financing activities	(600)	(1,900)
Increase (decrease) in cash flow	\$200	\$(100)
Cash at the beginning of the year	200	300
Cash at the end of the year	\$400	\$200

For Fictitious Corporation, for the current year:

$$\begin{aligned} \text{Basic earning power} &= \frac{\$2,000,000}{\$11,000,000} \\ &= 0.1818 \text{ or } 18.18\% \end{aligned}$$

For every dollar invested in assets, Fictitious earned about 18 cents in the current year. This measure deals with earnings from operations; it does not consider how these operations are financed.

Another return-on-assets ratio uses net income—operating earnings less interest and taxes—instead of earnings before interest and taxes:

$$\text{Return on assets} = \frac{\text{Net income}}{\text{Total assets}}$$

(In actual application the same term, return on assets, is often used to describe both ratios. It is only in the actual context or through an examination of the numbers themselves that we know which return ratio is presented. We use two different terms to describe these two return-on-asset ratios in this entry simply to avoid any confusion.)

For Fictitious in the current year:

$$\begin{aligned}\text{Return on assets} &= \frac{\$1,200,000}{\$11,000,000} \\ &= 0.1091 \text{ or } 10.91\%\end{aligned}$$

Thus, without taking into consideration how assets are financed, the return on assets for Fictitious is 18%. Taking into consideration how assets are financed, the return on assets is 11%. The difference is due to Fictitious financing part of its total assets with debt, incurring interest of \$400,000 in the current year; hence, the return-on-assets ratio excludes taxes of \$400,000 in the current year from earnings in the numerator.

If we look at Fictitious's liabilities and equities, we see that the assets are financed in part by liabilities (\$1 million short term, \$4 million long term) and in part by equity (\$800,000 preferred stock, \$5.2 million common stock). Investors may not be interested in the return the firm gets from its total investment (debt plus equity), but rather shareholders are interested in the return the firm can generate on their investment. The *return on equity* is the ratio of the net income shareholders receive to their equity in the stock:

$$\begin{aligned}\text{Return on equity} & \\ &= \frac{\text{Net income}}{\text{Book value of shareholders' equity}}\end{aligned}$$

For Fictitious Corporation, there is only one type of shareholder: common. For the current year:

$$\begin{aligned}\text{Return on equity} &= \frac{\$1,200,000}{\$6,000,000} \\ &= 0.2000 \text{ or } 20.00\%\end{aligned}$$

Recap: Return-on-Investment Ratios

The return-on-investment ratios for Fictitious Corporation for the current year are:

$$\begin{aligned}\text{Basic earning power} &= 18.18\% \\ \text{Return on assets} &= 10.91\% \\ \text{Return on equity} &= 20.00\%\end{aligned}$$

These return-on-investment ratios indicate:

- Fictitious earns over 18% from operations, or about 11% overall, from its assets.
- Shareholders earn 20% from their investment (measured in book value terms).

These ratios do not provide information on:

- Whether this return is due to the profit margins (that is, due to costs and revenues) or to how efficiently Fictitious uses its assets.
- The return shareholders earn on their actual investment in the firm, that is, what shareholders earn relative to their actual investment, not the book value of their investment. For example, \$100 may be invested in the stock, but its value according to the balance sheet may be greater than or, more likely, less than \$100.

DuPont System

The returns on investment ratios provides a "bottom line" on the performance of a company, but do not tell us anything about the "why" behind this performance. For an understanding of the "why," an analyst must dig a bit deeper into the financial statements. A method that is useful in examining the source of performance is the DuPont system. The DuPont system is a method of breaking down return ratios into their components to determine which areas are responsible for a firm's performance. To see how it is used, let us take a closer look at the first definition of the return on assets:

$$\begin{aligned}\text{Basic earning power} & \\ &= \frac{\text{Earnings before interest and taxes}}{\text{Total assets}}\end{aligned}$$

Suppose the return on assets changes from 20% in one period to 10% the next period. We do not know whether this decreased return is due to a less efficient use of the firm's assets—that is, lower activity—or to less effective management of expenses (that is, lower profit margins). A lower return on assets could be due to lower activity, lower margins, or both. Because an analyst is interested in evaluating past operating performance to evaluate different aspects of the management of the firm and to predict future performance, knowing the source of these returns is valuable.

Let us take a closer look at the return on assets and break it down into its components: measures of activity and profit margin. We do this by relating both the numerator and the denominator to sales activity. Divide both the numerator and the denominator of the basic earning power by revenues:

$$\text{Basic earning power} = \frac{\text{Earnings before interest and taxes/Revenues}}{\text{Revenues total assets/Revenues}}$$

which is equivalent to:

$$\text{Basic earning power} = \left(\frac{\text{Earnings before interest and taxes}}{\text{Revenues}} \right) \left(\frac{\text{Revenues}}{\text{Revenues total assets}} \right)$$

This says that the earning power of the company is related to profitability (in this case, operating profit) and a measure of activity (total asset turnover).

$$\begin{aligned} \text{Basic earning power} &= (\text{Operating profit margin}) \\ &(\text{Total asset turnover}) \end{aligned}$$

When analyzing a change in the company's basic earning power, an analyst could look at this breakdown to see the change in its components: operating profit margin and total asset turnover.

This method of analyzing return ratios in terms of profit margin and turnover ratios, re-

ferred to as the DuPont System, is credited to the E.I. DuPont Corporation, whose management developed a system of breaking down return ratios into their components.

Let's look at the return on assets of Fictitious for the two years. Its returns on assets were 20% in the prior year and 18.18% in the current year. We can decompose the firm's returns on assets for the two years to obtain:

Year	Basic Earning Power	Operating Profit Margin	Total Asset Turnover
Prior	20.00%	22.22%	0.9000 times
Current	18.18	20.00	0.9091 times

We see that operating profit margin declined over the two years, yet asset turnover improved slightly, from 0.9000 to 0.9091. Therefore, the return-on-assets decline is attributable to lower profit margins.

The return on assets can be broken down into its components in a similar manner:

$$\text{Return on assets} = \left(\frac{\text{Net income}}{\text{Revenues}} \right) \left(\frac{\text{Revenues}}{\text{Revenues total assets}} \right)$$

or

$$\begin{aligned} \text{Return on assets} &= (\text{Net profit margin})(\text{Total asset turnover}) \end{aligned}$$

The basic earning power ratio relates to the return on assets. Recognizing that:

$$\text{Net income} = \text{Earnings before tax}(1 - \text{Tax rate})$$

then

$$\begin{aligned} \text{Net income} &= \text{Earnings before interest and taxes} \\ &\times \left(\frac{\text{Earnings before taxes}}{\text{Earnings before interest and taxes}} \right) (1 - \text{Tax rate}) \\ &\quad \uparrow \quad \quad \quad \uparrow \\ &\quad \text{equity's share of earnings} \quad \text{tax retention \%} \end{aligned}$$

The ratio of earnings before taxes to earnings before interest and taxes reflects the interest burden of the company, whereas the term $(1 - \text{tax rate})$ reflects the company's tax burden.

Therefore,

$$\begin{aligned} \text{Return on assets} &= \left(\frac{\text{Earnings before interest and taxes}}{\text{Revenues}} \right) \\ &\times \left(\frac{\text{Revenues}}{\text{Revenues total assets}} \right) \\ &\times \left(\frac{\text{Earnings before taxes}}{\text{Earnings before interest and taxes}} \right) \\ &\quad (1 - \text{Tax rate}) \end{aligned}$$

or

$$\begin{aligned} \text{Return on assets} &= (\text{Operating profit margin})(\text{Total asset turnover}) \\ &\times (\text{Equity's share of earnings})(\text{Tax retention \%}) \end{aligned}$$

The breakdown of a return-on-equity ratio requires a bit more decomposition because instead of total assets as the denominator, the denominator in the return is shareholders' equity. Because activity ratios reflect the use of all of the assets, not just the proportion financed by equity, we need to adjust the activity ratio by the proportion that assets are financed by equity (that is, the ratio of the book value of shareholders' equity to total assets):

$$\begin{aligned} \text{Return on equity} &= (\text{Return on assets}) \left(\frac{\text{Total assets}}{\text{Shareholder's equity}} \right) \\ &= \left(\frac{\text{Net income}}{\text{Revenues}} \right) \left(\frac{\text{Revenues}}{\text{Total assets}} \right) \left(\frac{\text{Total assets}}{\text{Shareholder's equity}} \right) \\ &\quad \uparrow \\ &\quad \text{Equity multiplier} \end{aligned}$$

The ratio of total assets to shareholders' equity is referred to as the *equity multiplier*. The equity multiplier, therefore, captures the effects of how a company finances its assets, referred to as its financial leverage. Multiplying the total asset turnover ratio by the equity multiplier allows us to break down the return-on-equity ratios into three components: profit margin, asset turnover, and financial leverage. For example, the return on equity can be broken down

into three parts:

$$\begin{aligned} \text{Return on equity} &= (\text{Net profit margin})(\text{Total asset turnover}) \\ &\quad (\text{Equity multiplier}) \end{aligned}$$

Applying this breakdown to Fictitious for the two years:

Year	Return on Equity	Net Profit Margin	Total Asset Turnover	Total Debt to Assets	Equity Multiplier
Prior	22.73%	11.11%	0.9000 times	56.00%	2.2727
Current	20.00	12.00	0.9091	45.45%	1.8332

The return on equity decreased over the two years because of a lower operating profit margin and less use of financial leverage.

The analyst can decompose the return on equity further by breaking out the equity's share of before-tax earnings (represented by the ratio of earnings before and after interest) and tax retention percentage. Consider the example in Figure 1, in which we provide a DuPont breakdown of the return on equity for Microsoft Corporation for the fiscal year ending June 30, 2006, in Panel A. The return on equity of 31.486% can be broken down into three and then five components, as shown in this figure. We can also use this breakdown to compare the return on equity for the 2005 and 2006 fiscal years, as shown in Panel B. As you can see, the return on equity improved from 2005 to 2006 and, using this breakdown, we can see that this was due primarily to the improvement in the asset turnover and the increased financial leverage.

This decomposition allows the analyst to take a closer look at the factors that are controllable by a company's management (e.g., asset turnover) and those that are not controllable (e.g., tax retention). The breakdowns lead the analyst to information on both the balance sheet and the income statement. And this is not the only breakdown of the return ratios—further decomposition is possible.

For the fiscal year ending June 30, 2006,

$$\text{Return on equity} = \frac{\text{Net income}}{\text{Total assets}} = \frac{\$12.599}{\$40.014} = 0.31486 \text{ or } 31.486\%$$

Breaking return on equity into three components:

$$\begin{aligned} \text{Return on equity} &= \frac{\text{Net income}}{\text{Revenues}} \times \frac{\text{Revenues}}{\text{Total assets}} \times \frac{\text{Total assets}}{\text{Shareholders' equity}} \\ &= \frac{\$12.599}{\$44.282} \times \frac{\$44.282}{\$69.597} \times \frac{\$69.597}{\$40.014} = 0.31486 \text{ or } 31.486\% \end{aligned}$$

Breaking the return on equity into five components:

$$\begin{aligned} \text{Return on equity} &= \left(\frac{\text{Earnings before interest and taxes}}{\text{Revenues}} \right) \times \left(\frac{\text{Earnings before taxes}}{\text{Earnings before interest and taxes}} \right) \times (1 - \text{Tax rate}) \times \left(\frac{\text{Revenues}}{\text{Total assets}} \right) \times \left(\frac{\text{Total assets}}{\text{Shareholders' equity}} \right) \\ \text{Return on equity} &= \left(\frac{\$18.262}{\$44.282} \right) \times \left(\frac{\$18.262}{\$18.262} \right) \times (1 - 0.31010) \times \left(\frac{\$44.282}{\$69.597} \right) \times \left(\frac{\$69.597}{\$40.014} \right) \\ &= 0.41240 \times 1.0 \times 0.68990 \times 0.63626 \times 1.73932 \\ &= 0.31486 \text{ or } 31.486\% \end{aligned}$$

Comparing the components between the June 30, 2006 fiscal year and the June 30, 2005 fiscal year,

$$\text{Return on equity} = \left(\frac{\text{Earnings before interest and taxes}}{\text{Revenues}} \right) \times \left(\frac{\text{Earnings before taxes}}{\text{Earnings before interest and taxes}} \right) \times (1 - \text{Tax rate}) \times \left(\frac{\text{Revenues}}{\text{Total assets}} \right) \times \left(\frac{\text{Total assets}}{\text{Shareholders' equity}} \right)$$

$$\text{Return on equity June 30, 2006} = 0.41240 \times 1.0 \times 0.68990 \times 0.63626 \times 1.73932 = 31.486\%$$

$$\text{Return on equity June 30, 2005} = 0.41791 \times 1.0 \times 0.73695 \times 0.56186 \times 1.47179 = 25.468\%$$

Figure 1 The DuPont System Applied to Microsoft Corporation

LIQUIDITY

Liquidity reflects the ability of a firm to meet its short-term obligations using those assets that are most readily converted into cash. Assets that may be converted into cash in a short period of time are referred to as *liquid assets*; they are listed in financial statements as current assets. Current assets are often referred to as *working capital*, since they represent the resources needed for the day-to-day operations of the firm's long-term capital investments. Current assets are used to satisfy short-term obligations, or current liabilities. The amount by which current assets exceed current liabilities is referred to as the *net working capital*.

Operating Cycle

How much liquidity a firm needs depends on its *operating cycle*. The operating cycle is the duration from the time cash is invested in goods

and services to the time that investment produces cash. For example, a firm that produces and sells goods has an operating cycle comprising four phases:

1. Purchase raw materials and produce goods, investing in inventory.
2. Sell goods, generating sales, which may or may not be for cash.
3. Extend credit, creating accounts receivable.
4. Collect accounts receivable, generating cash.

The four phases make up the cycle of cash use and generation. The operating cycle would be somewhat different for companies that produce services rather than goods, but the idea is the same—the operating cycle is the length of time it takes to generate cash through the investment of cash.

What does the operating cycle have to do with liquidity? The longer the operating cycle, the more current assets are needed

(relative to current liabilities) since it takes longer to convert inventories and receivables into cash. In other words, the longer the operating cycle, the greater the amount of net working capital required.

To measure the length of an operating cycle we need to know:

- The time it takes to convert the investment in inventory into sales (that is, cash → inventory → sales → accounts receivable).
- The time it takes to collect sales on credit (that is, accounts receivable → cash).

We can estimate the operating cycle for Fictitious Corporation for the current year, using the balance sheet and income statement data. The number of days Fictitious ties up funds in inventory is determined by the total amount of money represented in inventory and the average day's cost of goods sold. The current investment in inventory—that is, the money “tied up” in inventory—is the ending balance of inventory on the balance sheet. The *average day's cost of goods sold* is the cost of goods sold on an average day in the year, which can be estimated by dividing the cost of goods sold (which is found on the income statement) by the number of days in the year. The average day's cost of goods sold for the current year is:

$$\begin{aligned} & \text{Average day's cost of goods sold} \\ &= \frac{\text{Cost of goods sold}}{365 \text{ days}} \\ &= \frac{\$6,500,000}{365 \text{ days}} \\ &= \$17,808 \text{ per day} \end{aligned}$$

In other words, Fictitious incurs, on average, a cost of producing goods sold of \$17,808 per day.

Fictitious has \$1.8 million of inventory on hand at the end of the year. How many days' worth of goods sold is this? One way to look at this is to imagine that Fictitious stopped buying more raw materials and just finished producing whatever was on hand in inventory, using available raw materials and work-in-process.

How long would it take Fictitious to run out of inventory?

We compute the days sales in inventory (DSI), also known as the *number of days of inventory*, by calculating the ratio of the amount of inventory on hand (in dollars) to the average day's cost of goods sold (in dollars per day):

$$\begin{aligned} & \text{Days sales in inventory} \\ &= \frac{\text{Amount of inventory on hand}}{\text{Average day's cost of goods sold}} \\ &= \frac{\$1,800,000}{\$17,808 \text{ per day}} = 101 \text{ days} \end{aligned}$$

In other words, Fictitious has approximately 101 days of goods on hand at the end of the current year. If sales continued at the same price, it would take Fictitious 101 days to run out of inventory.

If the ending inventory is representative of the inventory throughout the year, then it takes about 101 days to convert the investment in inventory into sold goods. Why worry about whether the year-end inventory is representative of inventory at any day throughout the year? Well, if inventory at the end of the fiscal year-end is lower than on any other day of the year, we have understated the DSI. Indeed, in practice most companies try to choose fiscal year-ends that coincide with the slow period of their business. That means the ending balance of inventory would be lower than the typical daily inventory of the year. To get a better picture of the firm, we could, for example, look at quarterly financial statements and take averages of quarterly inventory balances. However, here for simplicity we make a note of the problem of representatives and deal with it later in the discussion of financial ratios.

It should be noted that as an attempt to make the inventory figure more representative, some suggest taking the average of the beginning and ending inventory amounts. This does nothing to remedy the representativeness problem because the beginning inventory is simply the ending inventory from the previous year and, like the ending value from the current year, is

measured at the low point of the operating cycle. A preferred method, if data are available, is to calculate the average inventory for the four quarters of the fiscal year.

We can extend the same logic for calculating the number of days between a sale—when an account receivable is created—and the time it is collected in cash. If we assume that Fictitious sells all goods on credit, we can first calculate the *average credit sales per day* and then figure out how many days' worth of credit sales are represented by the ending balance of receivables.

The average credit sales per day are:

$$\begin{aligned}\text{Credit sales per day} &= \frac{\text{Credit sales}}{365 \text{ days}} \\ &= \frac{\$10,000,000}{365 \text{ days}} \\ &= \$27,397 \text{ per day}\end{aligned}$$

Therefore, Fictitious generates \$27,397 of credit sales per day. With an ending balance of accounts receivable of \$600,000, the *days sales outstanding* (DSO), also known as the *number of days of credit*, in this ending balance is calculated by taking the ratio of the balance in the accounts receivable account to the credit sales per day:

$$\begin{aligned}\text{Days sales outstanding} &= \frac{\text{Accounts receivable}}{\text{Credit sales per day}} \\ &= \frac{\$600,000}{\$27,397 \text{ per day}} \\ &= 22 \text{ days}\end{aligned}$$

If the ending balance of receivables at the end of the year is representative of the receivables on any day throughout the year, then it takes, on average, approximately 22 days to collect the accounts receivable. In other words, it takes 22 days for a sale to become cash.

Using what we have determined for the inventory cycle and cash cycle, we see that for Fictitious:

$$\begin{aligned}\text{Operating cycle} &= \text{DSI} + \text{DSO} \\ &= 101 \text{ days} + 22 \text{ days} \\ &= 123 \text{ days}\end{aligned}$$

We also need to look at the liabilities on the balance sheet to see how long it takes a firm to pay its short-term obligations. We can apply the same logic to accounts payable as we did to accounts receivable and inventories. How long does it take a firm, on average, to go from creating a payable (buying on credit) to paying for it in cash?

First, we need to determine the amount of an *average day's purchases on credit*. If we assume all the Fictitious purchases are made on credit, then the total purchases for the year would be the cost of goods sold less any amounts included in cost of goods sold that are not purchases. For example, depreciation is included in the cost of goods sold yet is not a purchase. Since we do not have a breakdown on the company's cost of goods sold showing how much was paid for in cash and how much was on credit, let us assume for simplicity that purchases are equal to cost of goods sold less depreciation. The average day's purchases then become:

$$\begin{aligned}\text{Average day's purchases} &= \frac{\text{Cost of goods sold} - \text{Depreciation}}{365 \text{ days}} \\ &= \frac{\$6,500,000 - \$1,000,000}{365 \text{ days}} \\ &= \$15,068 \text{ per day}\end{aligned}$$

The *days payables outstanding* (DPO), also known as the number of days of purchases, represented in the ending balance in accounts payable, is calculated as the ratio of the balance in the accounts payable account to the average day's purchases:

$$\begin{aligned}\text{Days payables outstanding} &= \frac{\text{Accounts payable}}{\text{Average day's purchases}}\end{aligned}$$

For Fictitious in the current year:

$$\begin{aligned}\text{Days payables outstanding} &= \frac{\$500,000}{\$15,065 \text{ per day}} \\ &= 33 \text{ days}\end{aligned}$$

This means that on average Fictitious takes 33 days to pay out cash for a purchase.

The operating cycle tells us how long it takes to convert an investment in cash back into cash (by way of inventory and accounts receivable). The number of days of payables tells us how long it takes to pay on purchases made to create the inventory. If we put these two pieces of information together, we can see how long, on net, we tie up cash. The difference between the operating cycle and the number of days of purchases is the *cash conversion cycle* (CCC), also known as the *net operating cycle*:

$$\text{Cash conversion cycle} = \text{Operating cycle} \\ - \text{DPO}$$

Or, substituting for the operating cycle,

$$\text{CCC} = \text{DSI} + \text{DSO} - \text{DPO}$$

The cash conversion cycle for Fictitious in the current year is:

$$\text{CCC} = 101 + 22 - 33 = 90 \text{ days}$$

The CCC is how long it takes for the firm to get cash back from its investments in inventory and accounts receivable, considering that purchases may be made on credit. By not paying for purchases immediately (that is, using trade credit), the firm reduces its liquidity needs. Therefore, the longer the net operating cycle, the greater the required liquidity.

Measures of Liquidity

The analyst can describe a firm's ability to meet its current obligations in several ways. The *current ratio* indicates the firm's ability to meet or cover its current liabilities using its current assets:

$$\text{Current ratio} = \frac{\text{Current assets}}{\text{Current liabilities}}$$

For the Fictitious Corporation, the current ratio for the current year is the ratio of current assets, \$3 million, to current liabilities, the sum of accounts payable and other current liabilities,

or \$1 million.

$$\text{Current ratio} = \frac{\$3,000,000}{\$1,000,000} = 3.0 \text{ times}$$

The current ratio of 3.0 indicates that Fictitious has three times as much as it needs to cover its current obligations during the year. However, the current ratio groups all current asset accounts together, assuming they are all as easily converted to cash. Even though, by definition, current assets can be transformed into cash within a year, not all current assets can be transformed into cash in a short period of time.

An alternative to the current ratio is the *quick ratio*, also called the *acid-test ratio*, which uses a slightly different set of current accounts to cover the same current liabilities as in the current ratio. In the quick ratio, the least liquid of the current asset accounts, inventory, is excluded. Hence:

$$\text{Quick ratio} = \frac{\text{Current assets} - \text{Inventory}}{\text{Current liabilities}}$$

We typically leave out inventories in the quick ratio because inventories are generally perceived as the least liquid of the current assets. By leaving out the least liquid asset, the quick ratio provides a more conservative view of liquidity.

For Fictitious in the current year:

$$\begin{aligned} \text{Quick ratio} &= \frac{\$3,000,000 - \$1,800,000}{\$1,000,000} \\ &= \frac{\$1,200,000}{\$1,000,000} = 1.2 \text{ times} \end{aligned}$$

Still another way to measure the firm's ability to satisfy short-term obligations is the *net working capital-to-sales ratio*, which compares net working capital (current assets less current liabilities) with sales:

$$\begin{aligned} \text{Net working capital-to-sales ratio} \\ &= \frac{\text{Net working capital}}{\text{Sales}} \end{aligned}$$

This ratio tells us the "cushion" available to meet short-term obligations relative to sales. Consider two firms with identical working capital of \$100,000, but one has sales of \$500,000 and

the other sales of \$1 million. If they have identical operating cycles, this means that the firm with the greater sales has more funds flowing in and out of its current asset investments (inventories and receivables). The company with more funds flowing in and out needs a larger cushion to protect itself in case of a disruption in the cycle, such as a labor strike or unexpected delays in customer payments. The longer the operating cycle, the more of a cushion (net working capital) a firm needs for a given level of sales.

For Fictitious Corporation:

$$\begin{aligned} \text{Net working capital-to-sales-ratio} \\ = \frac{\$3,000,000 - 1,000,000}{\$10,000,000} = 0.2000 \text{ or } 20\% \end{aligned}$$

The ratio of 0.20 tells us that for every dollar of sales, Fictitious has 20 cents of net working capital to support it.

Recap: Liquidity Ratios

Operating cycle and liquidity ratio information for Fictitious using data for the current year, in summary, is:

Days sales in inventory	= 101 days
Days sales outstanding	= 22 days
Operating cycle	= 123 days
Days payables outstanding	= 33 days
Cash conversion cycle	= 90 days
Current ratio	= 3.0
Quick ratio	= 1.2
Net working capital-to-sales ratio	= 20%

Given the measures of time related to the current accounts—the operating cycle and the cash conversion cycle—and the three measures of liquidity—current ratio, quick ratio, and net working capital-to-sales ratio—we know the following about Fictitious Corporation’s ability to meet its short-term obligations:

- Inventory is less liquid than accounts receivable (comparing days of inventory with days of credit).

- Current assets are greater than needed to satisfy current liabilities in a year (from the current ratio).
- The quick ratio tells us that Fictitious can meet its short-term obligations even without resorting to selling inventory.
- The net working capital “cushion” is 20 cents for every dollar of sales (from the net working capital-to-sales ratio.)

What don’t ratios tell us about liquidity? They don’t provide us with answers to the following questions:

- How liquid are the accounts receivable? How much of the accounts receivable will be collectible? Whereas we know it takes, on average, 22 days to collect, we do not know how much will never be collected.
- What is the nature of the current liabilities? How much of current liabilities consists of items that recur (such as accounts payable and wages payable) each period and how much consists of occasional items (such as income taxes payable)?
- Are there any unrecorded liabilities (such as operating leases) that are not included in current liabilities?

PROFITABILITY RATIOS

Liquidity ratios indicate a firm’s ability to meet its immediate obligations. Now we extend the analysis by adding *profitability ratios*, which help the analyst gauge how well a firm is managing its expenses. *Profit margin ratios* compare components of income with sales. They give the analyst an idea of which factors make up a firm’s income and are usually expressed as a portion of each dollar of sales. For example, the profit margin ratios we discuss here differ only in the numerator. It is in the numerator that we can evaluate performance for different aspects of the business.

For example, suppose the analyst wants to evaluate how well production facilities are managed. The analyst would focus on gross

profit (sales less cost of goods sold), a measure of income that is the direct result of production management. Comparing gross profit with sales produces the *gross profit margin*:

$$\begin{aligned} \text{Gross profit margin} \\ = \frac{\text{Revenues} - \text{Cost of goods sold}}{\text{Revenues}} \end{aligned}$$

This ratio tells us the portion of each dollar of sales that remains after deducting production expenses. For Fictitious Corporation for the current year:

$$\begin{aligned} \text{Gross profit margin} &= \frac{\$10,000,000 - \$6,500,000}{\$10,000,000} \\ &= \frac{\$3,500,000}{\$10,000,000} \\ &= 0.3500 \text{ or } 35\% \end{aligned}$$

For each dollar of revenues, the firm's gross profit is 35 cents. Looking at sales and cost of goods sold, we can see that the gross profit margin is affected by:

- Changes in sales volume, which affect cost of goods sold and sales.
- Changes in sales price, which affect revenues.
- Changes in the cost of production, which affect cost of goods sold.

Any change in gross profit margin from one period to the next is caused by one or more of those three factors. Similarly, differences in gross margin ratios among firms are the result of differences in those factors.

To evaluate operating performance, we need to consider operating expenses in addition to the cost of goods sold. To do this, remove operating expenses (e.g., selling and general administrative expenses) from gross profit, leaving operating profit, also referred to as earnings before interest and taxes (EBIT). The *operating profit margin* is therefore:

$$\begin{aligned} \text{Operating profit margin} \\ = \frac{\text{Revenues} - \text{Cost of goods sold} - \text{Operating expenses}}{\text{Revenues}} \\ = \frac{\text{Revenues earnings before interest and taxes}}{\text{Revenues}} \end{aligned}$$

For Fictitious in the current year:

$$\begin{aligned} \text{Operating profit margin} &= \frac{\$2,000,000}{\$10,000,000} \\ &= 0.20 \text{ or } 20\% \end{aligned}$$

Therefore, for each dollar of revenues, Fictitious has 20 cents of operating income. The operating profit margin is affected by the same factors as gross profit margin, plus operating expenses such as:

- Office rent and lease expenses
- Miscellaneous income (e.g., income from investments)
- Advertising expenditures
- Bad debt expense

Most of these expenses are related in some way to revenues, though they are not included directly in the cost of goods sold. Therefore, the difference between the gross profit margin and the operating profit margin is due to these indirect items that are included in computing the operating profit margin.

Both the gross profit margin and the operating profit margin reflect a company's operating performance. But they do not consider how these operations have been financed. To evaluate both operating and financing decisions, the analyst must compare net income (that is, earnings after deducting interest and taxes) with revenues. The result is the *net profit margin*:

$$\text{Net profit margin} = \frac{\text{Net income}}{\text{Revenues}}$$

The net profit margin tells the analyst the net income generated from each dollar of revenues; it considers financing costs that the operating profit margin does not consider. For Fictitious for the current year:

$$\text{Net profit margin} = \frac{\$1,200,000}{\$10,000,000} = 0.12 \text{ or } 12\%$$

For every dollar of revenues, Fictitious generates 12 cents in profits.

Recap: Profitability Ratios

The profitability ratios for Fictitious in the current year are:

Gross profit margin	= 35%
Operating profit margin	= 20%
Net profit margin	= 12%

They indicate the following about the operating performance of Fictitious:

- Each dollar of revenues contributes 35 cents to gross profit and 20 cents to operating profit.
- Every dollar of revenues contributes 12 cents to owners' earnings.
- By comparing the 20-cent operating profit margin with the 12-cent net profit margin, we see that Fictitious has 8 cents of financing costs for every dollar of revenues.

What these ratios do not indicate about profitability is the sensitivity of gross, operating, and net profit margins to:

- Changes in the sales price
- Changes in the volume of sales

Looking at the profitability ratios for one firm for one period gives the analyst very little information that can be used to make judgments regarding future profitability. Nor do these ratios provide the analyst any information about why current profitability is what it is. We need more information to make these kinds of judgments, particularly regarding the future profitability of the firm. For that, turn to activity ratios, which are measures of how well assets are being used.

ACTIVITY RATIOS

Activity ratios—for the most part, turnover ratios—can be used to evaluate the benefits produced by specific assets, such as inventory or accounts receivable, or to evaluate the benefits produced by the totality of the firm's assets.

Inventory Management

The *inventory turnover ratio* indicates how quickly a firm has used inventory to generate

the goods and services that are sold. The inventory turnover is the ratio of the cost of goods sold to inventory:

$$\text{Inventory turnover ratio} = \frac{\text{Cost of goods sold}}{\text{Inventory}}$$

For Fictitious for the current year:

$$\begin{aligned} \text{Inventory turnover ratio} &= \frac{\$6,500,000}{\$1,800,000} \\ &= 3.61 \text{ times} \end{aligned}$$

This ratio indicates that Fictitious turns over its inventory 3.61 times per year. On average, cash is invested in inventory, goods and services are produced, and these goods and services are sold 3.6 times a year. Looking back to the number of days of inventory, we see that this turnover measure is consistent with the results of that calculation: There are 101 calendar days of inventory on hand at the end of the year; dividing 365 days by 101 days, or 365/101 days, we find that inventory cycles through (from cash to sales) 3.61 times a year.

Accounts Receivable Management

In much the same way inventory turnover can be evaluated, an analyst can evaluate a firm's management of its accounts receivable and its credit policy. The *accounts receivable turnover ratio* is a measure of how effectively a firm is using credit extended to customers. The reason for extending credit is to increase sales. The downside to extending credit is the possibility of default—customers not paying when promised. The benefit obtained from extending credit is referred to as *net credit sales*—sales on credit less returns and refunds.

$$\begin{aligned} \text{Accounts receivable turnover} \\ &= \frac{\text{Net credit sales}}{\text{Accounts receivable}} \end{aligned}$$

Looking at the Fictitious Corporation income statement, we see an entry for sales, but we do not know how much of the amount stated is on credit. In the case of evaluating a firm, an analyst would have an estimate of the amount

of credit sales. Let us assume that the entire sales amount represents net credit sales. For Fictitious for the current year:

$$\begin{aligned}\text{Accounts receivable turnover} &= \frac{\$10,000,000}{\$600,000} \\ &= 16.67 \text{ times}\end{aligned}$$

Therefore, almost 17 times in the year there is, on average, a cycle that begins with a sale on credit and finishes with the receipt of cash for that sale. In other words, there are 17 cycles of sales to credit to cash during the year.

The number of times accounts receivable cycle through the year is consistent with the days sales outstanding (22) that we calculated earlier—accounts receivable turn over 17 times during the year, and the average number of days of sales in the accounts receivable balance is $365 \text{ days} / 16.67 \text{ times} = 22 \text{ days}$.

Overall Asset Management

The inventory and accounts receivable turnover ratios reflect the benefits obtained from the use of specific assets (inventory and accounts receivable). For a more general picture of the productivity of the firm, an analyst can compare the sales during a period with the total assets that generated these revenues.

One way is with the *total asset turnover ratio*, which indicates how many times during the year the value of a firm's total assets is generated in revenues:

$$\text{Total assets turnover} = \frac{\text{Revenues}}{\text{Total assets}}$$

For Fictitious in the current year:

$$\begin{aligned}\text{Total assets turnover} &= \frac{\$10,000,000}{\$11,000,000} \\ &= 0.91 \text{ times}\end{aligned}$$

The turnover ratio of 0.91 indicated that in the current year, every dollar invested in total assets generates 91 cents of sales. Or, stated differently, the total assets of Fictitious turn over almost once during the year. Because total as-

sets include both tangible and intangible assets, this turnover indicates how efficiently all assets were used.

An alternative is to focus only on fixed assets, the long-term, tangible assets of the firm. The *fixed-asset turnover* is the ratio of revenues to fixed assets:

$$\text{Fixed asset turnover ratio} = \frac{\text{Revenues}}{\text{Fixed assets}}$$

For Fictitious in the current year:

$$\begin{aligned}\text{Fixed asset turnover ratio} &= \frac{\$10,000,000}{\$7,000,000} \\ &= 1.43 \text{ times}\end{aligned}$$

Therefore, for every dollar of fixed assets, Fictitious is able to generate \$1.43 of revenues.

Recap: Activity Ratios

The activity ratios for Fictitious Corporation are:

Inventory turnover ratio	= 3.61 times
Accounts receivable turnover ratio	= 16.67 times
Total asset turnover ratio	= 0.91 times
Fixed-asset turnover ratio	= 1.43 times

From these ratios the analyst can determine that:

- Inventory flows in and out almost four times a year (from the inventory turnover ratio).
- Accounts receivable are collected in cash, on average, 22 days after a sale (from the number of days of credit). In other words, accounts receivable flow in and out almost 17 times during the year (from the accounts receivable turnover ratio).

Here is what these ratios do not indicate about the firm's use of its assets:

- The sales not made because credit policies are too stringent.
- How much of credit sales is not collectible.
- Which assets contribute most to the turnover.

FINANCIAL LEVERAGE RATIOS

A firm can finance its assets with equity or with debt. Financing with debt legally obligates the firm to pay interest and to repay the principal as promised. Equity financing does not obligate the firm to pay anything because dividends are paid at the discretion of the board of directors. There is always some risk, which we refer to as business risk, inherent in any business enterprise. But how a firm chooses to finance its operations—the particular mix of debt and equity—may add financial risk on top of business risk. *Financial risk* is risk associated with a firm's ability to satisfy its debt obligations, and is often measured using the extent to which debt financing is used relative to equity.

Financial leverage ratios are used to assess how much financial risk the firm has taken on. There are two types of financial leverage ratios: component percentages and coverage ratios. Component percentages compare a firm's debt with either its total capital (debt plus equity) or its equity capital. Coverage ratios reflect a firm's ability to satisfy fixed financing obligations, such as interest, principal repayment, or lease payments.

Component Percentage Ratios

A ratio that indicates the proportion of assets financed with debt is the *debt-to-assets ratio*, which compares total liabilities (short-term + long-term debt) with total assets:

$$\text{Total debt-to-assets ratio} = \frac{\text{Debt}}{\text{Total assets}}$$

For Fictitious in the current year:

$$\begin{aligned} \text{Total debt-to-assets ratio} &= \frac{\$5,000,000}{\$11,000,000} \\ &= 0.4546 \text{ or } 45.46\% \end{aligned}$$

This ratio indicates that 45% of the firm's assets are financed with debt (both short term and long term).

Another way to look at the financial risk is in terms of the use of debt relative to the use of eq-

uity. The debt-to-equity ratio indicates how the firm finances its operations with debt relative to the book value of its shareholders' equity:

$$\begin{aligned} \text{Debt-to-equity ratio} \\ &= \frac{\text{Debt}}{\text{Book value of shareholders' equity}} \end{aligned}$$

For Fictitious for the current year, using the book-value definition:

$$\begin{aligned} \text{Debt-to-equity ratio} &= \frac{\$5,000,000}{\$6,000,000} \\ &= 0.8333 \text{ or } 83.33\% \end{aligned}$$

For every \$1 of book value of shareholders' equity, Fictitious uses 83 cents of debt.

Both of these ratios can be stated in terms of total debt, as above, or in terms of long-term debt or even simply interest-bearing debt. And it is not always clear in which form—total, long-term debt, or interest-bearing—the ratio is calculated. Additionally, it is often the case that the current portion of long-term debt is excluded in the calculation of the long-term versions of these debt ratios.

Book Value versus Market Value

One problem with using a financial ratio based on the book value of equity to analyze financial risk is that there is seldom a strong relationship between the book value and market value of a stock. The distortion in values on the balance sheet is obvious by looking at the book value of equity and comparing it with the market value of equity. The book value of equity consists of:

- The proceeds to the firm of all the stock issues since it was first incorporated, less any stock repurchased by the firm.
- The accumulative earnings of the firm, less any dividends, since it was first incorporated.

Let's look at an example of the book value versus the market value of equity. IBM was incorporated in 1911, so the book value of its equity represents the sum of all its stock issued and all its earnings, less any dividends paid since 1911. As of the end of 2006, IBM's book value of

equity was approximately \$28.5 billion, yet its market value was \$142.8 billion.

Book value generally does not give a true picture of the investment of shareholders in the firm because:

- Earnings are recorded according to accounting principles, which may not reflect the true economics of transactions.
- Due to inflation, the earnings and proceeds from stock issued in the past do not reflect today's values.

Market value, on the other hand, is the value of equity as perceived by investors. It is what investors are willing to pay. So why bother with book value? For two reasons: First, it is easier to obtain the book value than the market value of a firm's securities, and second, many financial services report ratios using book value rather than market value.

However, any of the ratios presented in this entry that use the book value of equity can be restated using the market value of equity. For example, instead of using the book value of equity in the debt-to-equity ratio, the market value of equity to measure the firm's financial leverage can be used.

Coverage Ratios

The ratios that compare debt to equity or debt to assets indicate the amount of financial leverage, which enables an analyst to assess the financial condition of a firm. Another way of looking at the financial condition and the amount of financial leverage used by the firm is to see how well it can handle the financial burdens associated with its debt or other fixed commitments.

One measure of a firm's ability to handle financial burdens is the *interest coverage ratio*, also referred to as the *times interest-covered ratio*. This ratio tells us how well the firm can cover or meet the interest payments associated with debt. The ratio compares the funds available to pay interest (that is, earnings before interest and taxes)

with the interest expense:

$$\text{Interest coverage ratio} = \frac{\text{EBIT}}{\text{Interest expense}}$$

The greater the interest coverage ratio, the better able the firm is to pay its interest expense.

For Fictitious for the current year:

$$\text{Interest coverage ratio} = \frac{\$2,000,000}{\$400,000} = 5 \text{ times}$$

An interest coverage ratio of 5 means that the firm's earnings before interest and taxes are five times greater than its interest payments.

The interest coverage ratio provides information about a firm's ability to cover the interest related to its debt financing. However, there are other costs that do not arise from debt but that nevertheless must be considered in the same way we consider the cost of debt in a firm's financial obligations. For example, lease payments are fixed costs incurred in financing operations. Like interest payments, they represent legal obligations.

What funds are available to pay debt and debt-like expenses? Start with EBIT and add back expenses that were deducted to arrive at EBIT. The ability of a firm to satisfy its fixed financial costs—its fixed charges—is referred to as the *fixed-charge coverage ratio*. One definition of the fixed-charge coverage considers only the lease payments:

$$\begin{aligned} \text{Fixed-charge coverage ratio} \\ = \frac{\text{EBIT} + \text{Lease expense}}{\text{Interest} + \text{Lease expense}} \end{aligned}$$

For Fictitious for the current year:

$$\begin{aligned} \text{Fixed-charge coverage ratio} \\ = \frac{\$2,000,000 + \$1,000,000}{\$400,000 + \$1,000,000} \\ = 2.14 \text{ times} \end{aligned}$$

This ratio tells us that Fictitious's earnings can cover its fixed charges (interest and lease payments) more than two times over.

What fixed charges to consider is not entirely clear-cut. For example, if the firm is required to set aside funds to eventually or periodically

retire debt—referred to as sinking funds—is the amount set aside a fixed charge? As another example, since preferred dividends represent a fixed financing charge, should they be included as a fixed charge? From the perspective of the common shareholder, the preferred dividends must be covered either to enable the payment of common dividends or to retain earnings for future growth. Because debt principal repayment and preferred stock dividends are paid on an after-tax basis—paid out of dollars remaining after taxes are paid—this fixed charge must be converted to before-tax dollars. The fixed charge coverage ratio can be expanded to accommodate the sinking funds and preferred stock dividends as fixed charges.

Up to now we considered earnings before interest and taxes as funds available to meet fixed financial charges. EBIT includes noncash items such as depreciation and amortization. If an analyst is trying to compare funds available to meet obligations, a better measure of available funds is cash flow from operations, as reported in the statement of cash flows. A ratio that considers cash flows from operations as funds available to cover interest payments is referred to as the *cash-flow interest coverage ratio*.

$$\text{Cash flow interest coverage ratio} = \frac{\text{Cash flow from operations} + \text{Interest} + \text{Taxes}}{\text{Interest}}$$

The amount of cash flow from operations that is in the statement of cash flows is net of interest and taxes. So we have to add back interest and taxes to cash flow from operations to arrive at the cash flow amount before interest and taxes in order to determine the cash flow available to cover interest payments.

For Fictitious for the current year:

$$\begin{aligned} \text{Cash flow interest coverage ratio} &= \frac{\$1,800,000 + \$400,000 + \$400,000}{\$400,000} \\ &= \frac{\$2,600,000}{\$400,000} = 6.5 \text{ times} \end{aligned}$$

This coverage ratio indicates that, in terms of cash flows, Fictitious has 6.5 times more cash than is needed to pay its interest. This is a better picture of interest coverage than the five times reflected by EBIT. Why the difference? Because cash flow considers not just the accounting income, but noncash items as well. In the case of Fictitious, depreciation is a non-cash charge that reduced EBIT but not cash flow from operations—it is added back to net income to arrive at cash flow from operations.

Recap: Financial Leverage Ratios

Summarizing, the financial leverage ratios for Fictitious Corporation for the current year are:

Debt-to-assets ratio	= 45.45%
Debt-to-equity ratio	= 83.33%
Interest coverage ratio	= 5.00 times
Fixed-charge coverage ratio	= 2.14 times
Cash-flow interest coverage ratio	= 6.50 times

These ratios indicate that Fictitious uses its financial leverage as follows:

- Assets are 45% financed with debt, measured using book values.
- Long-term debt is approximately two-thirds of equity. When equity is measured in market value terms, long-term debt is approximately one-sixth of equity.

These ratios do not indicate:

- What other fixed, legal commitments the firm has that are not included on the balance sheet (for example, operating leases).
- What the intentions of management are regarding taking on more debt as the existing debt matures.

COMMON-SIZE ANALYSIS

An analyst can evaluate a company's operating performance and financial condition through ratios that relate various items of information contained in the financial statements. Another

way to analyze a firm is to look at its financial data more comprehensively.

Common-size analysis is a method of analysis in which the components of a financial statement are compared with each other. The first step in common-size analysis is to break down a financial statement—either the balance sheet or the income statement—into its parts. The next step is to calculate the proportion that each item represents relative to some benchmark. This form of common-size analysis is sometimes referred to as *vertical common-size analysis*. Another form of common-size analysis is *horizontal common-size analysis*, which uses either an income statement or a balance sheet in a fiscal year and compares accounts to the corresponding items in another year. In common-size analysis of the balance sheet, the benchmark is total assets. For the income statement, the benchmark is sales.

Let us see how it works by doing some common-size financial analysis for the Fictitious Corporation. The company's balance sheet is restated in Table 4. This statement does not look precisely like the balance sheet we have seen before. Nevertheless, the data are the same but reorganized. Each item in the original balance sheet has been restated as a proportion

Table 4 Fictitious Corporation Common-Size Balance Sheets for Years Ending December 31

	Current Year	Prior Year
Asset Components		
Cash	3.6%	2.0%
Marketable securities	1.8%	0.0%
Accounts receivable	5.5%	8.0%
Inventory	<u>16.4%</u>	<u>10.0%</u>
Current assets	27.3%	20.0%
Net plant and equipment	63.5%	70.0%
Intangible assets	<u>9.2%</u>	<u>10.0%</u>
Total assets	100.0%	100.0%
Liability and shareholders' equity components		
Accounts payable	4.6%	4.0%
Other current liabilities	4.6%	2.0%
Long-term debt	<u>36.4%</u>	<u>50.0%</u>
Total liabilities	45.4%	56.0%
Shareholders' equity	<u>54.6%</u>	<u>44.0%</u>
Total liabilities and shareholders' equity	100.0%	100.0%

of total assets for the purpose of common size analysis. Hence, we refer to this as the *common-size balance sheet*.

In this balance sheet, we see, for example, that in the current year cash is 3.6% of total assets, or $\$400,000/\$11,000,000 = 0.036$. The largest investment is in plant and equipment, which comprises 63.6% of total assets. On the liabilities side, that current liabilities are a small portion (9.1%) of liabilities and equity.

The common-size balance sheet indicates in very general terms how Fictitious has raised capital and where this capital has been invested. As with financial ratios, however, the picture is not complete until trends are examined and compared with those of other firms in the same industry.

In the income statement, as with the balance sheet, the items may be restated as a proportion of sales; this statement is referred to as the *common-size income statement*. The common-size income statements for Fictitious for the two years are shown in Table 5. For the current year, the major costs are associated with goods sold (65%); lease expense, other expenses, interest, taxes, and dividends make up smaller portions of sales. Looking at gross profit, EBIT, and net income, these proportions are the profit margins we calculated earlier. The common-size income statement provides information on the profitability of different aspects of the firm's business. Again, the picture is not yet complete.

Table 5 Fictitious Corporation Common-Size Income Statement for Years Ending December 31

	Current Year	Prior Year
Sales	100.0%	100.0%
Cost of goods sold	<u>65.0%</u>	<u>66.7%</u>
Gross profit	35.0%	33.3%
Lease and administrative expenses	<u>15.0%</u>	<u>11.1%</u>
Earnings before interest and taxes	20.0%	22.2%
Interest expense	<u>4.0%</u>	<u>5.6%</u>
Earnings before taxes	16.0%	16.6%
Taxes	<u>4.0%</u>	<u>5.5%</u>
Net income	12.0%	11.1%
Common dividends	<u>6.0%</u>	<u>5.6%</u>
Retained earnings	6.0%	5.5%

For a more complete picture, the analyst must look at trends over time and make comparisons with other companies in the same industry.

USING FINANCIAL RATIO ANALYSIS

Financial analysis provides information concerning a firm's operating performance and financial condition. This information is useful for an analyst in evaluating the performance of the company as a whole, as well as of divisions, products, and subsidiaries. An analyst must also be aware that financial analysis is also used by analysts and investors to gauge the financial performance of the company.

But financial ratio analysis cannot tell the whole story and must be interpreted and used with care. Financial ratios are useful but, as noted in the discussion of each ratio, there is information that the ratios do not reveal. For example, in calculating inventory turnover, we need to assume that the inventory shown on the balance sheet is representative of inventory throughout the year. Another example is in the calculation of accounts receivable turnover. We assumed that all sales were on credit. If we are on the outside looking in—that is, evaluating a firm based on its financial statements only, such as the case of a financial analyst or investor—and therefore do not have data on credit sales, assumptions must be made that may or may not be correct.

In addition, there are other areas of concern that an analyst should be aware of in using financial ratios:

- Limitations in the accounting data used to construct the ratios.
- Selection of an appropriate benchmark firm or firms for comparison purposes.
- Interpretation of the ratios.
- Pitfalls in forecasting future operating performance and financial condition based on past trends.

KEY POINTS

- The basic data for financial analysis are the financial statement data. These data are used to analyze relationships between different elements of a firm's financial statements. Through this analysis, a picture of the operating performance and financial condition of a firm can be developed.
- Looking at the calculated financial ratios, in conjunction with industry and economic data, judgments about past and future financial performance and condition can be made.
- Financial ratios can be classified by type—coverage, return, turnover, or component percentage—or by the financial characteristic that we wish to measure—liquidity, profitability activity, financial leverage, or return.
- Liquidity ratios indicate firm's ability to satisfy short-term obligations. These ratios are closely related to a firm's operating cycle, which tells us how long it takes a firm to turn its investment in current assets back into cash.
- Profitability ratios indicate how well a firm manages its assets, typically in terms of the proportion of revenues that are left over after expenses.
- Activity ratios measure how efficiently a firm manages its assets, that is, how effectively a firm uses its assets to generate sales.
- Financial leverage ratios indicate (1) to what extent a firm uses debt to finance its operations and (2) its ability to satisfy debt and debt-like obligations.
- Return-on-investment ratios provide a gauge for how much of each dollar of an investment is generated in a period.
- The DuPont system breaks down return ratios into their profit margin and activity ratios, allowing us to analyze changes in return on investments.
- Common-size analysis expresses financial statement data relative to some benchmark item—usually total assets for the balance sheet and sales for the income statement. Representing financial data in this way allows

an analyst to spot trends in investments and profitability.

- Interpretation of financial ratios requires an analyst to put the trends and comparisons in perspective with the company's significant events. In addition to company-specific events, issues that can cause the analysis of financial ratios to become more challenging include the use of historical accounting values, changes in accounting principles, and accounts that are difficult to classify.
- Comparison of financial ratios across time and with competitors is useful in gauging performance. In comparing ratios over time, an analyst should consider changes in accounting and significant company events. In comparing ratios with a benchmark, an analyst

must take care in the selection of the companies that constitute the benchmark and the method of calculation.

Cash-Flow Analysis

PAMELA P. DRAKE, PhD, CFA

J. Gray Ferguson Professor of Finance, College of Business, James Madison University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: An objective of financial analysis is to assess a company's operating performance and financial condition. The information that is available for analysis includes economic, market, and financial information. But some of the most important financial data are provided by the company in its annual and quarterly financial statements. These choices make it quite difficult to compare financial performance and condition across companies, and also provide an opportunity for the management of financial numbers through judicious choice of accounting methods. Cash flows provide a way of transforming net income based on an accrual system to a more comparable basis. Additionally, cash flows are essential ingredients in valuation: The value of a company today is the present value of its expected future cash flows. Therefore, understanding past and current cash flows may help in forecasting future cash flows and, hence, determine the value of the company. Moreover, understanding cash flow allows the assessment of the ability of a firm to maintain current dividends and its current capital expenditure policy without relying on external financing.

One of the key financial measures that an analyst should understand is the company's cash flow. This is because the cash flow aids the analyst in assessing the ability of the company to satisfy its contractual obligations and maintain current dividends and current capital expenditure policy without relying on external financing. Moreover, an analyst must understand why this measure is important for external parties, specifically stock analysts covering the company. The reason is that the basic valuation principle followed by stock analysts is that the value of a company today is the present

value of its expected future cash flows. In this entry, we discuss *cash-flow analysis*.

DIFFICULTIES WITH MEASURING CASH FLOW

The primary difficulty with measuring a cash flow is that it is a flow: Cash flows into the company (cash inflows) and cash flows out of the company (cash outflows). At any point in time there is a stock of cash on hand, but the stock of cash on hand varies among companies because

of the size of the company, the cash demands of the business, and a company's management of working capital. So what is cash flow? Is it the total amount of cash flowing into the company during a period? Is it the total amount of cash flowing out of the company during a period? Is it the net of the cash inflows and outflows for a period? Well, there is no specific definition of cash flow—and that's probably why there is so much confusion regarding the measurement of cash flow. Ideally, a measure of the company's operating performance that is comparable among companies is needed—something other than net income.

A simple, yet crude method of calculating cash flow requires simply adding noncash expenses (e.g., depreciation and amortization) to the reported net income amount to arrive at cash flow. For example, the estimated cash flow for Procter & Gamble (P&G) for 2002 is:

$$\begin{aligned} &\text{Estimated cash flow} \\ &= \text{Net income} \quad + \quad \text{Depreciation and} \\ &\quad \quad \quad \text{amortization} \\ &= \$4,352 \text{ million} \quad + \quad 1,693 \text{ million} \\ &= \$6,045 \text{ million} \end{aligned}$$

This amount is not really a cash flow, but simply earnings before depreciation and amortization. Is this a cash flow that stock analysts should use in valuing a company? Though not a cash flow, this estimated cash flow does allow a quick comparison of income across firms that may use different depreciation methods and depreciable lives. (As an example of the use of this estimate of cash flow, *The Value Line Investment Survey*, published by Value Line, Inc., reports a cash flow per share amount, calculated as reported earnings plus depreciation, minus any preferred dividends, stated per share of common stock.) [*Guide to Using the Value Line Investment Survey* (New York: Value Line, Inc.), p. 19.]

The problem with this measure is that it ignores the many other sources and uses of cash during the period. Consider the sale of goods for credit. This transaction generates sales for

the period. Sales and the accompanying cost of goods sold are reflected in the period's net income and the estimated cash flow amount. However, until the account receivable is collected, there is no cash from this transaction. If collection does not occur until the next period, there is a misalignment of the income and cash flow arising from this transaction. Therefore, the simple estimated cash flow ignores some cash flows that, for many companies, are significant.

Another estimate of cash flow that is simple to calculate is earnings before interest, taxes, depreciation, and amortization (EBITDA). However, this measure suffers from the same accrual-accounting bias as the previous measure, which may result in the omission of significant cash flows. Additionally, EBITDA does not consider interest and taxes, which may also be substantial cash outflows for some companies. (For a more detailed discussion of the EBITDA measure, see Eastman [1997].)

These two rough estimates of cash flows are used in practice not only for their simplicity, but because they experienced widespread use prior to the disclosure of more detailed information in the statement of cash flows. Currently, the measures of cash flow are wide ranging, including the simplistic cash flow measures, measures developed from the statement of cash flows, and measures that seek to capture the theoretical concept of *free cash flow*.

CASH FLOWS AND THE STATEMENT OF CASH FLOWS

Prior to the adoption of the statement of cash flows, the information regarding cash flows was quite limited. The first statement that addressed the issue of cash flows was the statement of financial position, which was required starting in 1971 (APB Opinion No. 19, "Reporting Changes in Financial Position"). This statement was quite limited, requiring an analysis of the

sources and uses of funds in a variety of formats. In its earlier years of adoption, most companies provided this information using what is referred to as the *working capital concept*—a presentation of working capital provided and applied during the period. Over time, many companies began presenting this information using the *cash concept*, which is a most detailed presentation of the cash flows provided by operations, investing, and financing activities.

Consistent with the cash concept format of the funds flow statement, the statement of cash flows is now a required financial statement. The requirement that companies provide a statement of cash flows applies to fiscal years after 1987 (Statement of Financial Accounting Standards No. 95, “Statement of Cash Flows”). This statement requires the company to classify cash flows into three categories, based on the activity: operating, investing, and financing. Cash flows are summarized by activity and within activity by type (e.g., asset dispositions are reported separately from asset acquisitions).

The reporting company may report the cash flows from operating activities on the statement of cash flows using either the *direct method*—reporting all cash inflows and outflows—or the *indirect method*—starting with net income and making adjustments for depreciation and other noncash expenses and for changes in working capital accounts. Though the direct method is recommended, it is also the most burdensome for the reporting company to prepare. Most companies report cash flows from operations using the indirect method. The indirect method has the advantage of providing the financial statement user with a reconciliation of the company’s net income with the change in cash. The indirect method produces a cash flow from operations that is similar to the estimated cash flow measure discussed previously, yet it encompasses the changes in working capital accounts that the simple measure does not. For example, Procter & Gamble’s cash flow from operating activities (taken from their 2002 statement of cash flows) is \$7,742 million,

which is over \$1 billion more than the cash flow that we estimated earlier. (Procter & Gamble’s fiscal year ends June 30, 2002.)

The classification of cash flows into the three types of activities provides useful information that can be used by an analyst to see, for example, whether the company is generating sufficient cash flows from operations to sustain its current rate of growth. However, the classification of particular items is not necessarily as useful as it could be. Consider some of the classifications:

- Cash flows related to interest expense are classified in operations, though they are clearly financing cash flows.
- Income taxes are classified as operating cash flows, though taxes are affected by financing (e.g., deduction for interest expense paid on debt) and investment activities (e.g., the reduction of taxes from tax credits on investment activities).
- Interest income and dividends received are classified as operating cash flows, though these flows are a result of investment activities.

Whether these items have a significant effect on the analysis depends on the particular company’s situation. Procter & Gamble, for example, has very little interest and dividend income, and its interest expense of \$603 million is not large relative to its earnings before interest and taxes (\$6,986 million). Table 1 shows that by adjusting P&G’s cash flows for the interest expense only (and related taxes) changes the complexion of its cash flows slightly to reflect greater cash-flow generation from operations and less cash flow reliance on financing activities.

The adjustment is for \$603 million of interest and other financing costs, less its tax shield (the amount that the tax bill is reduced by the interest deduction) of \$211 (estimated from the average tax rate of 35% of \$603): adjustment = $\$603(1 - 0.35) = \392 .

Table 1 Adjusted Cash Flow for P&G (2002)

(In Millions)	As Reported	As Adjusted
Cash flow from operations	\$7,741	\$8,134
Cash flow for investing activities	(6,835)	(6,835)
Cash flow from (for) financing activities	197	(195)

Source: Procter & Gamble 2002 Annual Report.

For other companies, however, this adjustment may provide a less flattering view of cash flows. Consider Amazon.com's fiscal year results. Interest expense to financing, along with their respective estimated tax effects, results in more reliance on cash flow from financing as can be seen in Table 2.

Looking at the relation among the three cash flows in the statement provides a sense of the activities of the company. A young, fast-growing company may have negative cash flows from operations, yet positive cash flows from financing activities (that is, operations may be financed in large part with external financing). As a company grows, it may rely to a lesser extent on external financing. The typical, mature company generates cash from operations and reinvests part or all of it back into the company. Therefore, cash flow related to operations is positive (that is a source of cash) and cash flow related to investing activities is negative (that is, a use of cash). As a company matures, it may seek less financing externally and may even use cash to reduce its reliance on external financing (e.g., repay debts). We can classify companies on the basis of the pattern of their sources of cash flows, as shown in Table 3.

Table 2 Adjusted Cash Flow, Amazon.com (2001)

(In Millions)	As Reported	As Adjusted
Cash flow from operations	\$(120)	\$(30)
Cash flow for investing activities	(253)	(253)
Cash flow from financing activities	(107)	17

The adjustment is based on interest expense of \$139 million, and a tax rate of 35%.

Source: Amazon.com 2001 10-K.

Though additional information is required to assess a company's financial performance and condition, examination of the sources of cash flows, especially over time, gives us a general idea of the company's operations. P&G's cash flow pattern is consistent with that of a mature company, whereas Amazon.com's cash flows are consistent with those of a fast-growing company that is reliant on outside funds for growth.

Fridson (2002) suggests reformatting the statement of cash flows as shown in Table 4. From the basic cash flow, the nondiscretionary cash needs are subtracted resulting in a cash flow referred to as discretionary cash flow. By restructuring the statement of cash flows in this way, it can be seen how much flexibility the company has when it must make business decisions that may adversely impact the long-run financial health of the enterprise.

For example, consider a company with a basic cash flow of \$800 million and operating cash flow of \$500 million. Suppose that this company pays dividends of \$130 million and that its capital expenditure is \$300 million. Then the discretionary cash flow for this company is \$200 million found by subtracting the \$300 million capital expenditure from the operating cash flow of \$500 million. This means that even after maintaining a dividend payment of \$130 million, its cash flow is positive. Notice that asset sales and other investing activity are not needed to generate cash to meet the dividend payments because in Table 4 these items are subtracted after accounting for the dividend payments. In fact, if this company planned to increase its capital expenditures, the format in Table 4 can be used to assess how much that expansion can be before affecting dividends and/or increasing financing needs.

Though we can classify a company based on the sources and uses of cash flows, more data are needed to put this information in perspective. What is the trend in the sources and uses of cash flows? What market, industry, or company-specific events affect the company's cash flows? How does the company being

Table 3 Patterns of Sources of Cash Flows

Cash Flow	Financing Growth Externally and Internally	Financing Growth Internally	Mature	Temporary Financial Downturn	Financial Distress	Downsizing
Operations	+	+	+	-	-	+
Investing activities	-	-	-	+	-	+
Financing activities	+	-	+ or -	+	-	-

analyzed compare with other companies in the same industry in terms of the sources and uses of funds?

Let's take a closer look at the incremental information provided by cash flows. Consider Wal-Mart Stores, Inc., which had growing sales and net income from 1990 to 2005, as summarized in Figure 1. We see that net income grew each year, with the exception of 1995, and that sales grew each year.

We get additional information by looking at the cash flows and their sources, as graphed in Figure 2. We see that the growth in Wal-Mart was supported both by internally generated funds and, to a lesser extent, through external financing. Wal-Mart's pattern of cash flows suggests that Wal-Mart is a mature company that

has become less reliant on external financing, funding most of its growth in recent years (with the exception of 1999) with internally generated funds.

FREE CASH FLOW

Cash flows without any adjustment may be misleading because they do not reflect the cash outflows that are necessary for the future existence of a firm. An alternative measure, free cash flow, was developed by Jensen (1986) in his theoretical analysis of agency costs and corporate takeovers. In theory, free cash flow is the cash flow left over after the company funds all positive net present value projects. Positive net present value projects are those capital investment projects for which the present value of expected future cash flows exceeds the present value of project outlays, all discounted at the cost of capital. (The cost of capital is the cost to the company of funds from creditors and shareholders. The cost of capital is basically a hurdle: If a project returns more than its cost of capital, it is a profitable project.) In other words, free cash flow is the cash flow of the firm, less capital expenditures necessary to stay in business (that is, replacing facilities as necessary) and grow at the expected rate (which requires increases in working capital).

The theory of free cash flow was developed by Jensen to explain behaviors of companies that could not be explained by existing economic theories. Jensen observed that companies that generate free cash flow should disgorge that cash rather than invest the funds in less profitable investments. There are many ways in which companies can disgorge this

Table 4 Suggested Reformatting of Cash Flow Statement to Analyze a Company's Flexibility

	Basic cash flow
Less:	Increase in adjusted working capital
	Operating cash flow
Less:	Capital expenditures
	Discretionary cash flow
Less:	Dividends
Less:	Asset sales and other investing activities
	Cash flow before financing
Less:	Net (increase) in long-term debt
Less:	Net (increase) in notes payable
Less:	Net purchase of company's common stock
Less:	Miscellaneous
	Cash flow

Notes:

1. The basic cash flow includes net earnings, depreciation, and deferred income taxes, less items in net income not providing cash.
2. The increase in adjusted working capital excludes cash and payables.

Source: This format was suggested by Fridson (1995).

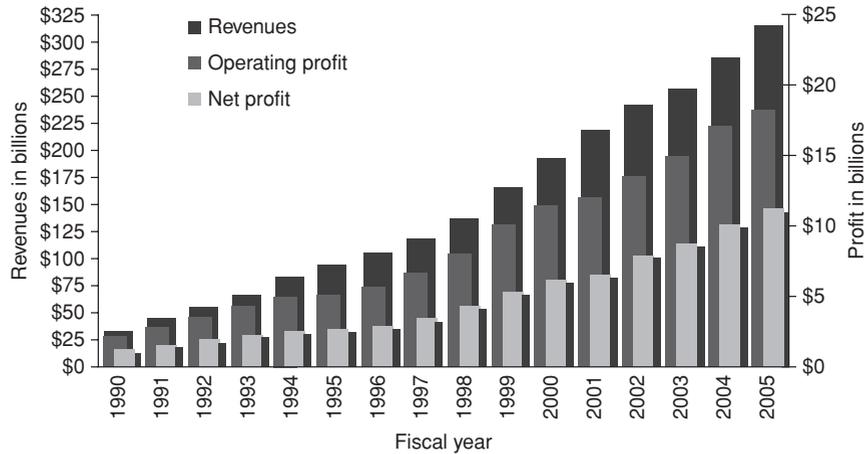

Figure 1 Wal-Mart Stores, Inc., Revenues, Operating Profit, and Net Income, 1990–2005
 Source: Wal-Mart Stores, Inc., Annual Report, various years.

excess cash flow, including the payment of cash dividends, the repurchase of stock, and debt issuance in exchange for stock. The debt-for-stock exchange, for example, increases the company’s leverage and future debt obligations, obligating the future use of excess cash flow. If a company does not disgorge this free cash flow, there is the possibility that another company—a company whose cash flows are less than its profitable investment opportunities or a company that is willing to purchase and lever-up the company—will attempt to acquire the free-cash-flow-laden company.

As a case in point, Jensen observed that the oil industry illustrates the case of wasting re-

sources: The free cash flows generated in the 1980s were spent on low-return exploration and development and on poor diversification attempts through acquisitions. He argues that these companies would have been better off paying these excess cash flows to shareholders through share repurchases or exchanges with debt.

By itself, the fact that a company generates free cash flow is neither good nor bad. What the company does with this free cash flow is what is important. And this is where it is important to measure the free cash flow as that cash flow in excess of profitable investment opportunities. Consider the simple numerical exercise

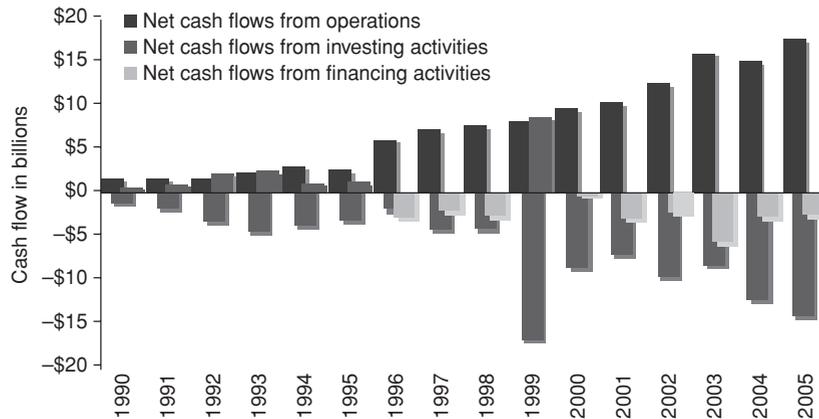

Figure 2 Wal-Mart Stores, Inc., Cash Flows, 1990–2005
 Source: Wal-Mart Stores, Inc., Annual Report, various years.

with the Winner Company and the Loser Company:

	Winner Company	Loser Company
Cash flow before capital expenditures	\$1,000	\$1,000
Capital expenditures, positive net present value projects	(750)	(250)
Capital expenditures, negative net present value projects	0	(500)
Cash flow	\$250	\$250
Free cash flow	\$250	\$750

These two companies have identical cash flows and the same total capital expenditures. However, the Winner Company spends only on profitable projects (in terms of positive net present value projects), whereas the Loser Company spends on both profitable projects and wasteful projects. The Winner Company has a lower free cash flow than the Loser Company, indicating that they are using the generated cash flows in a more profitable manner. The lesson is that the existence of a high level of free cash flow is not necessarily good—it may simply suggest that the company is either a very good takeover target or the company has the potential for investing in unprofitable investments.

Positive free cash flow may be good or bad news; likewise, negative free cash flow may be good or bad news:

	Good News	Bad News
Positive free cash flow	The company is generating substantial operating cash flows, beyond those necessary for profitable projects.	The company is generating more cash flows than it needs for profitable projects and may waste these cash flows on unprofitable projects.
Negative free cash flow	The company has more profitable projects than it has operating cash flows and must rely on external financing to fund these projects.	The company is unable to generate sufficient operating cash flows to satisfy its investment needs for future growth.

Therefore, once the free cash flow is calculated, other information (e.g., trends in profitability) must be considered to evaluate the operating performance and financial condition of the firm.

CALCULATING FREE CASH FLOW

There is some confusion when this theoretical concept is applied to actual companies. The primary difficulty is that the amount of capital expenditures necessary to maintain the business at its current rate of growth is generally not known; companies do not report this item and may not even be able to determine how much of a period's capital expenditures are attributed to maintenance and how much are attributed to expansion.

Consider Procter & Gamble's property, plant, and equipment for 2002, which comprise some, but not all, of P&G's capital investment:

Additions to property, plant, and equipment	\$1,679 million
Dispositions of property, plant, and equipment	(227)
Net change before depreciation	\$1,452 million

(In addition to the traditional capital expenditures (that is, changes in property, plant, and equipment), P&G also has cash flows related to investment securities and acquisitions. These investments are long-term and are hence part of P&G's investment activities cash outflow of \$6,835 million.)

How much of the \$1,679 million is for maintaining P&G's current rate of growth and how much is for expansion? Though there is a positive net change of \$1,452 million, does it mean that P&G is expanding? Not necessarily: The additions are at current costs, whereas the dispositions are at historical costs. The additions of \$1,679 are less than P&G's depreciation and amortization expense for 2001 of \$1,693 million, yet it is not disclosed in the financial reports how much of this latter amount reflects amortization. (P&G's depreciation and amortization

are reported together as \$1,693 million on the statement of cash flows.) The amount of necessary capital expenditures is therefore elusive.

Some estimate free cash flow by assuming that all capital expenditures are necessary for the maintenance of the current growth of the company. Though there is little justification in using all expenditures, this is a practical solution to an impractical calculation. This assumption allows us to estimate free cash flows using published financial statements.

Another issue in the calculation is defining what is truly “free” cash flow. Generally, we think of “free” cash flow as that being left over after all necessary financing expenditures are paid; this means that free cash flow is after interest on debt is paid. Some calculate free cash flow before such financing expenditures, others calculate free cash flow after interest, and still others calculate free cash flow after both interest and dividends (assuming that dividends are a commitment, though not a legal commitment).

There is no one correct method of calculating free cash flow and different analysts may arrive at different estimates of free cash flow for a company. The problem is that it is impossible to measure free cash flow as dictated by the theory, so many methods have arisen to calculate this cash flow. A simple method is to start with the cash flow from operations and then deduct capital expenditures. For P&G in 2002,

Cash flow from operations	\$7,742
Deduct capital expenditures	<u>(1,692)</u>
Free cash flow	\$6,050

Though this approach is rather simple, the cash flow from the operations amount includes a deduction for interest and other financing expenses. Making an adjustment for the after-tax interest and financing expenses, as we did earlier for Procter & Gamble,

Cash flow from operations (as reported)	\$7,742
Adjustment	<u>392</u>
Cash flow from operations (as adjusted)	\$8,134
Deduct capital expenditures	<u>(1,692)</u>
Free cash flow	\$6,442

We can relate free cash flow directly to a company’s income. Starting with net income, we can estimate free cash flow using four steps:

- Step 1: Determine earnings before interest and taxes (EBIT).
- Step 2: Calculate earnings before interest but after taxes.
- Step 3: Adjust for noncash expenses (e.g., depreciation).
- Step 4: Adjust for capital expenditures and changes in working capital.

Using these four steps, we can calculate the free cash flow for Procter & Gamble for 2002, as shown in Table 5.

NET FREE CASH FLOW

There are many variations in the calculation of cash flows that are used in analyses of companies’ financial condition and operating performance. As an example of these variations, consider the alternative to free cash flow developed by Fitch, a company that rates corporate debt instruments. This cash flow measure, referred to as *net free cash flow* (NFCF), is free cash flow less interest and other financing costs and taxes. In this approach, free cash flow is defined as earnings before depreciation, interest, and taxes, less capital expenditures. Capital expenditures encompass all capital spending, whether for maintenance or expansion, and no changes in working capital are considered.

The basic difference between NFCF and free cash flow is that the financing expenses—interest and, in some cases, dividends—are deducted. If preferred dividends are perceived as nondiscretionary—that is, investors come to expect the dividends—dividends may be included with the interest commitment to arrive at net free cash flow. Otherwise, dividends are deducted from net free cash flow to produce cash flow. Another difference is that NFCF does not consider changes in working capital in the analysis.

Table 5 Calculation of Procter & Gamble's Free Cash Flow for 2002, in Millions*

<i>Step 1:</i>		
Net income	\$4,352	
Add taxes	2,031	
Add interest	<u>603</u>	
Earnings before interest and taxes	\$6,986	
<i>Step 2:</i>		
Earnings before interest and taxes	\$6,986	
Deduct taxes (@35%)	<u>(2,445)</u>	
Earnings before interest	\$4,541	
<i>Step 3:</i>		
Earnings before interest	\$4,541	
Add depreciation and amortization	1,693	
Add increase in deferred taxes	<u>389</u>	
Earnings before noncash expenses	\$6,623	
<i>Step 4:</i>		
Earnings before noncash expenses		\$6,623
Deduct capital expenditures		<u>(1,679)</u>
Add decrease in receivables	\$96	
Add decrease in inventories	159	
Add cash flows from changes in accounts payable, accrued expenses, and other liabilities	684	
Deduct cash flow from changes in other operating assets and liabilities	<u>(98)</u>	
Cash flow from change in working capital accounts		<u>841</u>
Free cash flow		\$5,785

*Procter & Gamble's fiscal year ended June 30, 2002. Charges in operating accounts are taken from Procter & Gamble's Statement of Cash Flows.

Further, cash taxes are deducted to arrive at net free cash flow. Cash taxes are the income tax expense restated to reflect the actual cash flow related to this obligation, rather than the accrued expense for the period. Cash taxes are the income tax expense (from the income statement) adjusted for the change in deferred income taxes (from the balance sheets). For Procter & Gamble in 2002,

Income tax expense	\$2,031
Deduct increase in deferred income tax	<u>(389)</u>
Cash taxes	\$1,642

(Note that cash taxes require taking the tax expense and either increasing this to reflect any decrease in deferred taxes [that is, the payment this period of tax expense recorded in a prior period] or decreasing this amount to reflect any increase in deferred taxes [that is, the deferment of some of the tax expense].)

In the case of Procter & Gamble for 2002,

EBIT	\$6,986
Add depreciation and amortization	<u>1,693</u>
EBITDA	\$8,679
Deduct capital expenditures	<u>(1,679)</u>
Free cash flow	\$7,000
Deduct interest	(603)
Deduct cash taxes	<u>(1,642)</u>
Net free cash flow	\$4,755
Deduct cash common dividends	<u>(2,095)</u>
Net cash flow	\$2,660

The free cash flow amount per this calculation differs from the \$5,785 that we calculated earlier for two reasons: Changes in working capital and the deduction of taxes on operating earnings were not considered.

Net cash flow gives an idea of the unconstrained cash flow of the company. This cash flow measure may be useful from a creditor's perspective in terms of evaluating the company's ability to fund additional debt. From a

shareholder's perspective, net cash flow (that is, net free cash flow net of dividends) may be an appropriate measure because this represents the cash flow that is reinvested in the company.

USEFULNESS OF CASH FLOWS IN FINANCIAL ANALYSIS

The usefulness of cash flows for financial analysis depends on whether cash flows provide unique information or provide information in a manner that is more accessible or convenient for the analyst. The cash flow information provided in the statement of cash flows, for example, is not necessarily unique because most, if not all, of the information is available through analysis of the balance sheet and income statement. What the statement does provide is a classification scheme that presents information in a manner that is easier to use and, perhaps, more illustrative of the company's financial position.

An analysis of cash flows and the sources of cash flows can reveal the following information:

- **The sources of financing the company's capital spending.** Does the company generate in-

ternally (that is, from operations) a portion or all of the funds needed for its investment activities? If a company cannot generate cash flow from operations, this may indicate problems up ahead. Reliance on external financing (e.g., equity or debt issuance) may indicate a company's inability to sustain itself over time.

- **The company's dependence on borrowing.** Does the company rely heavily on borrowing that may result in difficulty in satisfying future debt service?
- **The quality of earnings.** Large and growing differences between income and cash flows suggest a low quality of earnings.

Consider the financial results of Krispy Kreme Doughnuts, Inc., a wholesaler and retailer of donuts. Krispy Kreme grew from having fewer than 200 stores before its initial public offering (IPO) in 2000 to over 400 stores at the end of its 2005 fiscal year. Accompanying this growth in stores is the growth in operating and net income, as we show in Figure 3. The growth in income continued after the IPO as the number of stores increased, but the tide in income turned in the 2004 fiscal year and losses continued into the 2005 fiscal year as well.

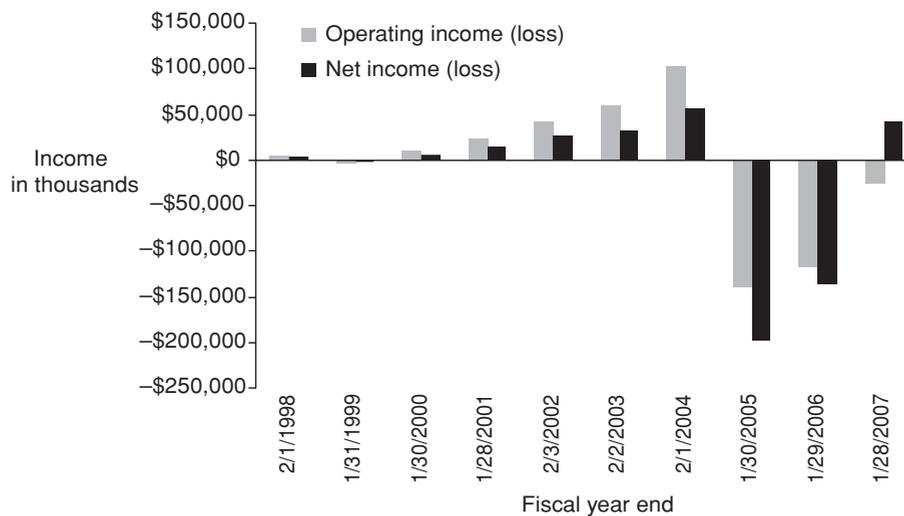

Figure 3 Krispy, Kreme Doughnuts, Inc. Income, 1997–2006
 Source: Krispy Kreme Doughnuts, Inc., 10-K filings, various years.

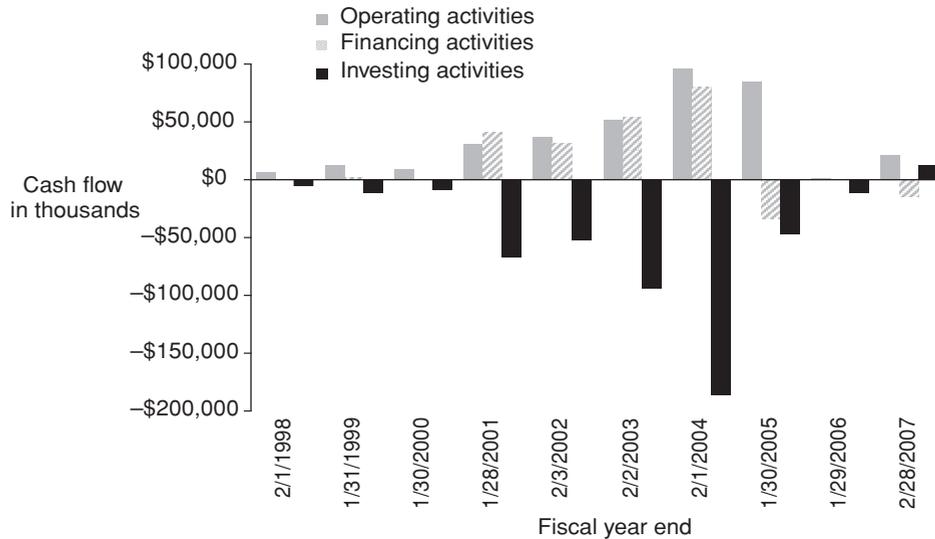

Figure 4 Krispy, Kreme Doughnuts, Inc., Cash Flows, 1997–2006
 Source: Krispy, Kreme Doughnuts, Inc., 10-K filings, various years.

Krispy Kreme's growth just after its IPO was financed by both operating activities and external financing, as we show in Figure 4. However, approximately half of the funds to support its rapid growth and to purchase some of its franchised stores in the 2000–2003 fiscal years came from long-term financing. This resulted in problems as the company's debt burden became almost three times its equity as revenue growth slowed by the 2005 fiscal year. Krispy Kreme demonstrated some ability to turn itself around in the 2006 fiscal year, partly by slowing its expansion through new stores.

Ratio Analysis

One use of cash-flow information is in ratio analysis, primarily with the balance sheet and income statement information. Once such ratio is the cash flow-based ratio, the *cash-flow interest coverage ratio*, which is a measure of financial risk. There are a number of other cash flow-based ratios that an analyst may find useful in evaluating the operating performance and financial condition of a company.

A useful ratio to help further assess a company's cash flow is the *cash flow-to-capital expenditures ratio*, or *capital expenditures coverage ratio*:

ditures ratio, or capital expenditures coverage ratio:

$$\begin{aligned} &\text{Cash flow-to-capital expenditures} \\ &= \frac{\text{Cash flow}}{\text{Capital expenditures}} \end{aligned}$$

The cash-flow measure in the numerator should be one that has not already removed capital expenditures; for example, including free cash flow in the numerator would be inappropriate.

This ratio provides information about the financial flexibility of the company and is particularly useful for capital-intensive firms and utilities (see Fridson, 2002, p. 173). The larger the ratio, the greater the financial flexibility. However, one must carefully examine the reasons why this ratio may be changing over time and why it might be out of line with comparable firms in the industry. For example, a declining ratio can be interpreted in two ways. First, the firm may eventually have difficulty adding to capacity via capital expenditures without the need to borrow funds. The second interpretation is that the firm may have gone through a period of major capital expansion and therefore it will take time for revenues to be generated

that will increase the cash flow from operations to bring the ratio to some normal long-run level.

Another useful cash flow ratio is the *cash flow-to-debt ratio*:

$$\text{Cash flow to debt} = \frac{\text{Cash flow}}{\text{Debt}}$$

where debt can be represented as total debt, long-term debt, or a debt measure that captures a specific range of maturity (e.g., debt maturing in five years). This ratio gives a measure of a company's ability to meet maturing debt obligations. A more specific formulation of this ratio is Fitch's CFAR ratio, which compares a company's three-year average net free cash flow to its maturing debt over the next five years (see McConville, 1996). By comparing the company's average net free cash flow to the expected obligations in the near term (that is, five years), this ratio provides information on the company's credit quality.

Using Cash-Flow Information

The analysis of cash flows provides information that can be used along with other financial data to help assess the financial condition of a company. Consider the cash flow-to-debt ratio calculated using three different measures of cash flow—EBITDA, free cash flow, and cash flow from operations (from the statement of cash flows)—each compared with long-term debt, as shown in Figure 5 for Weirton Steel.

This example illustrates the need to understand the differences among the cash flow measures. The effect of capital expenditures in the 1988–1991 period can be seen by the difference between the free-cash-flow measure and the other two measures of cash flow; both EBITDA and cash flow from operations ignore capital expenditures, which were substantial outflows for this company in the earlier period.

Cash-flow information may help a stock or bond analyst identify companies that may encounter financial difficulties. Consider the study by Largay and Stickney (1980) that an-

alyzed the financial statements of W. T. Grant during the 1966–1974 period preceding its bankruptcy in 1975 and ultimate liquidation. They noted that financial indicators such as profitability ratios, turnover ratios, and liquidity ratios showed some downtrends, but provided no definite clues to the company's impending bankruptcy. A study of cash flows from operations, however, revealed that company operations were causing an increasing drain on cash, rather than providing cash. (For the period investigated, a statement of changes of financial position [on a working capital basis]) was required to be reported prior to 1988.] This necessitated an increased use of external financing, the required interest payments on which exacerbated the cash-flow drain. Cash-flow analysis clearly was a valuable tool in this case since W. T. Grant had been running a negative cash flow from operations for years. Yet none of the traditional ratios discussed above take into account the cash flow from operations. Use of the cash flow-to-capital expenditures ratio and the cash flow-to-debt ratio would have highlighted the company's difficulties.

Dugan and Samson (1996) examined the use of operating cash flow as an early warning signal of a company's potential financial problems. The subject of the study was Allied Products Corporation because for a decade this company exhibited a significant divergence between cash flow from operations and net income. For parts of the period, net income was positive while cash flow from operations was a large negative value. In contrast to W. T. Grant, which went into bankruptcy, the auditor's report in the 1991 Annual Report of Allied Products Corporation did issue a going-concern warning. Moreover, the stock traded in the range of \$2 to \$3 per share. There was then a turnaround of the company by 1995. In its 1995 annual report, net income increased dramatically from prior periods (to \$34 million) and there was a positive cash flow from operations (\$29 million). The stock traded in the \$25 range by the spring of 1996. As with the W. T. Grant study, Dugan and

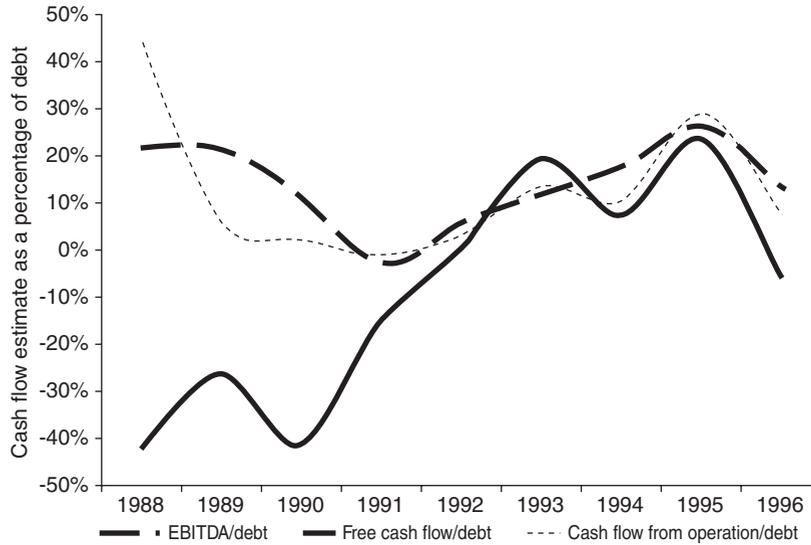

Figure 5 Cash Flow to Debt Using Alternative Estimates of Cash Flow for Weirton Steel, 1988–1996
Source: Weirton Steel's 10-K reports, various years.

Samson (1996) found that the economic realities of a firm are better reflected in its cash flow from operations.

The importance of cash-flow analysis in bankruptcy prediction is supported by the study by Foster and Ward (1997), who compared trends in the statement of cash flows components—cash flow from operations, cash flow for investment, and cash flow for financing—between healthy companies and companies that subsequently sought bankruptcy. They observe that healthy companies tend to have relatively stable relations among the cash flows for the three sources, correcting any given year's deviation from their norm within one year. They also observe that unhealthy companies exhibit declining cash flows from operations and financing and declining cash flows for investment one and two years prior to the bankruptcy. Further, unhealthy companies tend to expend more cash flows to financing sources than they bring in during the year prior to bankruptcy. These studies illustrate the importance of examining cash flow information in assessing the financial condition of a company.

KEY POINTS

- The term “cash flow” has many meanings and the challenge is to determine the cash-flow definition and calculation that is appropriate. The simplest calculation of cash flow is the sum of net income and noncash expenses. This measure, however, does not consider other sources and uses of cash during the period.
- The statement of cash flows provides a useful breakdown of the sources of cash flows: operating activities, investing activities, and financing activities. Though attention is generally focused on the cash flows from operations, what the company does with the cash flows (that is, investing or paying off financing obligations) and what the sources of invested funds are (that is, operations versus external financing) must be investigated. Minor adjustments can be made to the items classified in the statement of cash flows to improve the classification.
- Examination of the different patterns of cash flows is necessary to get a general idea of the activities of the company. For example, a company whose only source of cash flow is

from investing activities, suggesting the sale of property or equipment, may be experiencing financial distress.

- Free cash flow is a company's cash flow that remains after making capital investments that maintain the company's current rate of growth. It is not possible to calculate free cash flow precisely, resulting in many different variations in calculations of this measure. A company that generates free cash flow is not necessarily performing well or poorly; the existence of free cash flow must be taken in context with other financial data and information on the company.
- One of the variations in the calculation of a cash-flow measure is net free cash flow, which is, essentially, free cash flow less any financing obligations. This is a measure of the funds available to service additional obligations to suppliers of capital.

Abstract: Probability theory can be understood as a particular field in mathematics. Hence, it is only to be expected that it relies intensely on theory from analysis and algebra. For example, the fact that the cumulative probability over all values a random variable can assume has to be equal to one is not always feasible to check for without a profound knowledge of mathematics. Continuous probability distributions involve a good deal of analysis and the more sophisticated a distribution is, the more mathematics is necessary to handle it.

In this entry, we review the functions that are used in financial modeling: continuous functions, the indicator function, the derivative of a function, *monotonic functions*, and the integral. Moreover, as special functions, we get to know the factorial, the gamma, beta, and Bessel functions as well as the characteristic function of random variables. (For a more detailed discussion of these functions, see Khuri [2003], MacCluer [2009], and Richardson [2008].)

CONTINUOUS FUNCTION

In this section, we introduce general continuous functions.

General Idea

Let $f(x)$ be a *continuous function* for some real-valued variable x . The general idea behind continuity is that the graph of $f(x)$ does not exhibit gaps. In other words, $f(x)$ can be thought of as

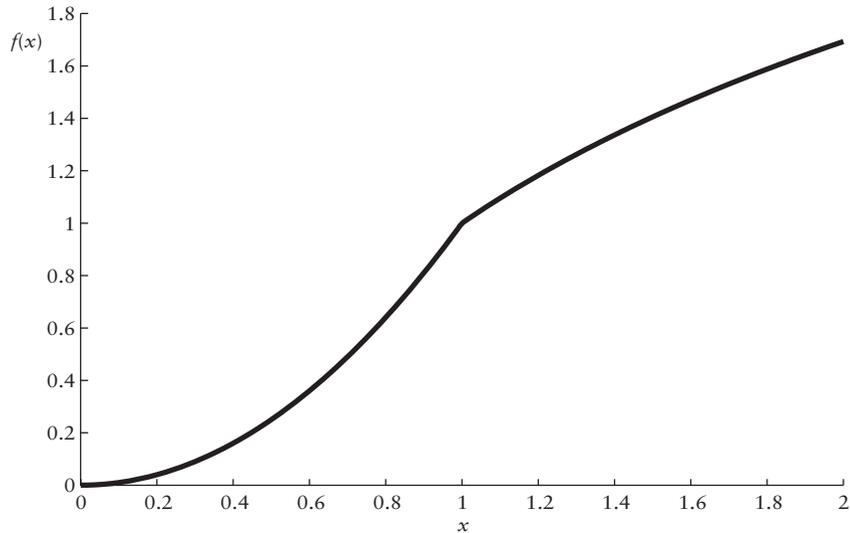

Figure 1 Continuous Function $f(x)$

Note: For $x \in [0,1)$, $f(x) = x^2$ and for $x \in [1,2)$, $f(x) = 1 + \ln(x)$.

being seamless. We illustrate this in Figure 1. For increasing x , from $x = 0$ to $x = 2$, we can move along the graph of $f(x)$ without ever having to jump. In the figure, the graph is generated by the two functions $f(x) = x^2$ for $x \in [0,1)$, and $f(x) = \ln(x) + 1$ for $x \in [1, 2)$.

Note that the function $f(x) = \ln(x)$ is the natural logarithm. It is the inverse function to the

exponential function $g(x) = e^x$ where $e = 2.7183$ is the Euler constant. The inverse has the effect that $f(g(x)) = \ln(e^x) = x$, that is, \ln and e cancel each other out.

A function $f(x)$ is discontinuous if we have to jump when we move along the graph of the function. For example, consider the graph in Figure 2. Approaching $x = 1$ from the left, we

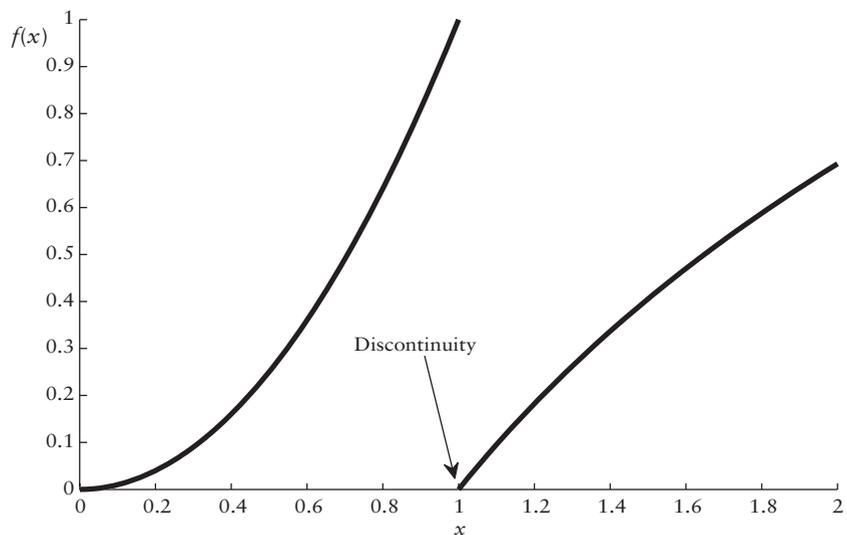

Figure 2 Discontinuous Function $f(x)$

Note: For $x \in [0,1)$, $f(x) = x^2$ and for $x \in [1,2)$, $f(x) = \ln(x)$.

have to jump from $f(x) = 1$ to $f(1) = 0$. Thus, the function f is discontinuous at $x = 1$. Here, f is given by $f(x) = x^2$ for $x \in [0,1)$, and $f(x) = \ln(x)$ for $x \in [1,2)$.

Formal Derivation

For a formal treatment of continuity, we first concentrate on the behavior of f at a particular value x^* .

We say that that a function $f(x)$ is *continuous* at x^* if, for any positive distance δ , we obtain a related distance $\varepsilon(\delta)$ such that

$$f(x^*) - \delta \leq f(x) \leq f(x^*) + \delta, \quad \text{for all } x \in (x^* - \varepsilon(\delta), x^* + \varepsilon(\delta))$$

What does that mean? We use Figure 3 to illustrate. (The function is $f(x) = \sin(x)$ with $x^* = 0.2$.) At x^* , we have the value $f(x^*)$. Now, we select a neighborhood around $f(x^*)$ of some arbitrary distance δ as indicated by the dashed horizontal lines through $f(x^*) - \delta$ and $f(x^*) + \delta$, respectively. From the intersections of these horizontal lines and the function graph (solid line),

we extend two vertical dash-dotted lines down to the x -axis so that we obtain the two values x^L and x^U , respectively. Now, we measure the distance between x^L and x^* and also the distance between x^U and x^* . The smaller of the two yields the distance $\varepsilon(\delta)$. With this distance $\varepsilon(\delta)$ on the x -axis, we obtain the environment $(x^* - \varepsilon(\delta), x^* + \varepsilon(\delta))$ about x^* . (Note that $x^L = x^* - \varepsilon(\delta)$, since the distance between x^L and x^* is the shorter one.) The environment is indicated by the dashed lines extending vertically above $x^* - \varepsilon(\delta)$ and $x^* + \varepsilon(\delta)$, respectively. We require that all x that lie in $(x^* - \varepsilon(\delta), x^* + \varepsilon(\delta))$ yield values $f(x)$ inside of the environment $[f(x^*) - \delta, f(x^*) + \delta]$. We can see by Figure 3 that this is satisfied.

Let us repeat this procedure for a smaller distance δ . We obtain new environments $[f(x^*) - \delta, f(x^*) + \delta]$ and $(x^* - \varepsilon(\delta), x^* + \varepsilon(\delta))$. If, for all x in $(x^* - \varepsilon(\delta), x^* + \varepsilon(\delta))$, the $f(x)$ are inside of $[f(x^*) - \delta, f(x^*) + \delta]$, again, then we can take an even smaller δ . We continue this for successively smaller values of δ just short of becoming 0 or until the condition on the $f(x)$ is no longer satisfied. As we can easily see in Figure 3, we could go on forever and the condition on the $f(x)$

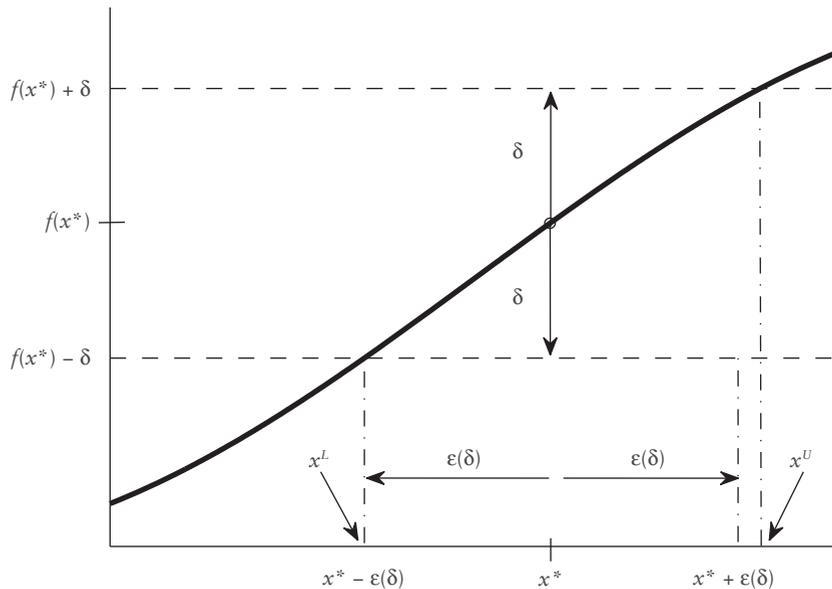

Figure 3 Continuity Criterion
 Note: Function $f = \sin(x)$, for $-1 \leq x \leq 1$.

would always be satisfied. Hence, the graph of f is seamless or continuous at x .

Finally, we say that the function f is *continuous* if it is continuous at all x for which f is defined, that is, in the domain of f . Note that only the domain of f is of interest. For example, the square root function $f(x) = \sqrt{x}$ is only defined for $x \geq 0$. Thus, we do not care about whether f is continuous for any x other than $x \geq 0$.

INDICATOR FUNCTION

The indicator function acts like a switch. Often, it is denoted by $1_A(X)$ where A is the event of interest and X is a random variable. So, $1_A(X)$ is 1 if the event A is true, that is, if X assumes a value in A . Otherwise, $1_A(X)$ is 0. Formally, this is expressed as

$$1_A(X) = \begin{cases} 1 & X \in A \\ 0 & \text{otherwise} \end{cases}$$

Usually, indicator functions are applied if we are interested in whether a certain event has occurred or not. For example, in a simple way,

the value V of a company may be described by a real numbered random variable X on $\Omega = \mathbf{R}$ with a particular probability distribution P . Now, the value V of the company may be equal to X as long as X is greater than 0. In the case where X assumes a negative value or 0, then V is automatically 0, that is, the company is bankrupt. So, the event of interest is $A = [0, \infty)$, that is, we want to know whether X is still positive. Using the indicator function this can be expressed as

$$1_{[0, \infty)}(X) = \begin{cases} 1 & X \in [0, \infty) \\ 0 & \text{otherwise} \end{cases}$$

Finally, the company value can be given as

$$V = 1_{[0, \infty)}(X) \cdot X = \begin{cases} X & X \in [0, \infty) \\ 0 & \text{otherwise} \end{cases}$$

The company value V as a function is depicted in Figure 4. We can clearly detect the kink at $x = 0$ where the indicator function becomes 1 and, hence, $V = X$.

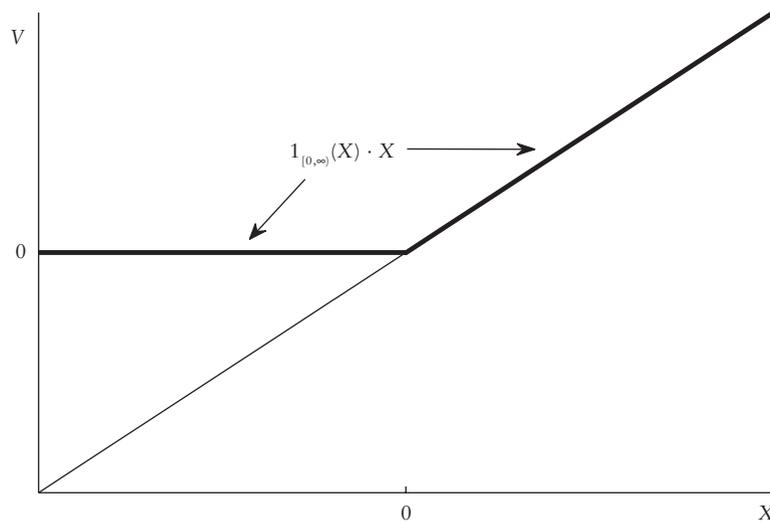

Figure 4 The Company Value V as a Function of the Random Variable X Using the Indicator Function $1_{[0, \infty)}(X) \cdot X$

DERIVATIVES

Suppose we have some continuous function f with the graph given by the solid line in Figure 5. We now might be interested in the growth rate of f at some position x . That is, we might want to know by how much f increases or decreases

when we move from some x by a step of a given size, say Δx , to the right. This difference in f we denote by Δf . This Δ symbol is called delta.

Let us next have a look at the graphs given by the solid lines in Figure 6. These represent the graphs of f and g . The important difference

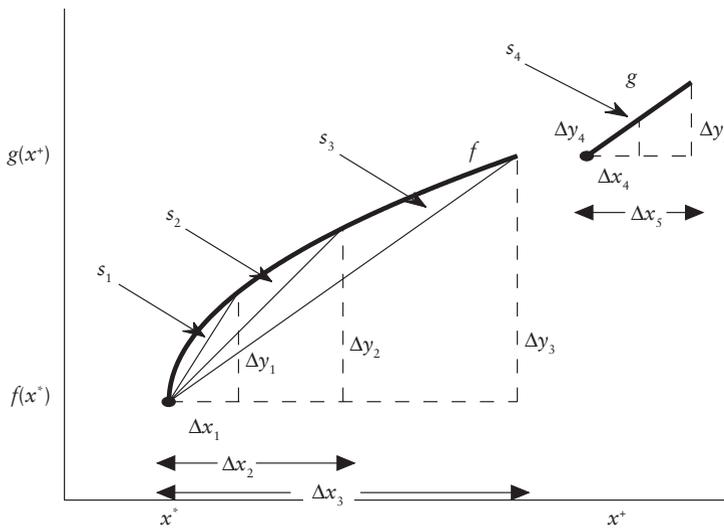

Figure 6 Functions f and g with Slopes Measured at the Points $(x^*, f(x^*))$ and $(x^+, g(x^+))$ Indicated by the \bullet Symbol

between f and g is that, while g is linear, f is not, as can be seen by f 's curvature.

We begin the analysis of the graphs' slopes with function g on the top right of the figure. Let us focus on the point $(x^+, g(x^+))$ given by the solid circle at the lower end of graph g . Now, when we move to the right by Δx_4 along the horizontal dashed line, the corresponding increase in g is given by Δy_4 , as indicated by the vertical dashed line. If, on the other hand, we moved to the right by the longer distance, Δx_5 , the according increment of g would be given by Δy_5 . (This vertical increment Δy_5 is also indicated by a vertical dashed line.) Since g is linear, it has constant slope everywhere and, hence, also at the point $(x^+, f(x^+))$. We denote that slope by s_4 . This implies that the ratios representing the relative increments (i.e., the slopes) have to be equal. That is,

$$s_4 = \frac{\Delta y_4}{\Delta x_4} = \frac{\Delta y_5}{\Delta x_5}$$

Next, we focus on the graph of f on the lower left of Figure 6. Suppose we measured the slope of f at the point $(x^*, f(x^*))$. If we extended a step along the dashed line to the right by Δx_1 , the corresponding increment in f would be Δy_1 , as indicated by the leftmost vertical dashed line. If we moved, instead, by the longer Δx_2 to the right, the corresponding increment in f would be Δy_2 . And a horizontal increment of Δx_3 would result in an increase of f by Δy_3 .

In contrast to the graph of g , the graph of f does not exhibit the property of a constant increment Δy in f per unit step Δx to the right. That is, there is no constant slope of f , which results in the fact that the three ratios of the relative increase of f are different. To be precise, we have

$$\frac{\Delta y_1}{\Delta x_1} > \frac{\Delta y_2}{\Delta x_2} > \frac{\Delta y_3}{\Delta x_3}$$

as can be seen in Figure 6. So, the shorter our step Δx to the right, the steeper the slopes of the thin solid lines through $(x^*, f(x^*))$ and the corresponding points on the curve, $(x^* + \Delta x_1, f(x^* + \Delta x_1))$, $(x^* + \Delta x_2, f(x^* + \Delta x_2))$, and $(x^* + \Delta x_2,$

$f(x^* + \Delta x_2))$, respectively. That means that, the smaller the increment Δx , the higher the relative increment Δy of f . So, finally, if we moved only a minuscule step to the right from $(x^*, f(x^*))$, we would obtain the steepest thin line and, consequently, the highest relative increase in f given by

$$\frac{\Delta y}{\Delta x} \quad (1)$$

By letting Δx approach 0, we obtain the marginal increment, in case the limit of (1) exists (i.e., if the ratio has a finite limit). Formally,

$$\frac{\Delta y}{\Delta x} \xrightarrow{\Delta x \rightarrow 0} s(x) \quad \text{with} \quad -\infty < s(x) < \infty$$

This marginal increment $s(x)$ is different, at any point on the graph of f , while we have seen that it is constant for all points on the graph of g .

Construction of the Derivative

The limit analysis of marginal increments now brings us to the notion of a *derivative* that we discuss next. Earlier we introduced the limit growth rate of some continuous function at some point $(x_0, f(x_0))$. To represent the slope of the line through $(x_0, f(x_0))$ and $(x_0 + \Delta x, f(x_0 + \Delta x))$, we define the difference quotient

$$\frac{f(x_0 + \Delta x) - f(x_0)}{\Delta x} \quad (2)$$

If we let $\Delta x \rightarrow 0$, we obtain the limit of the difference quotient (2). If this limit is not finite, then we say that it does not exist. Suppose we were not only interested in the behavior of f when moving Δx to the right but also wanted to analyze the reaction by f to a step Δx to the left. We would then obtain two limits of (2). The first with $\Delta x^+ > 0$ (i.e., a step to the right) would be the upper limit L^U

$$\frac{f(x_0 + \Delta x^+) - f(x_0)}{\Delta x^+} \xrightarrow{\Delta x^+ \rightarrow 0} L^U$$

and the second with $\Delta x^- < 0$ (i.e., a step to the left), would be the lower limit L^L

$$\frac{f(x_0 + \Delta x^-) - f(x_0)}{|\Delta x^-|} \xrightarrow{\Delta x^- \rightarrow 0} L^L$$

If L^U and L^L are equal, $L^U = L^L = L$, then f is said to be differentiable at x_0 . The limit L is the *derivative* of f . We commonly write the derivative in the fashion

$$f'(x_0) = \left. \frac{df(x)}{dx} \right|_{x=x_0} = \left. \frac{dy}{dx} \right|_{x=x_0} \quad (3)$$

On the right side of (3), we have replaced $f(x)$ by the variable y as we will often do, for convenience. If the derivative (3) exists for all x , then f is said to be differentiable.

Let us now return to Figure 5. Recall that the graph of the continuous function f is given by the solid line. We start at $x = -1$. Since f is not continuous at $x = -1$, we omit this end point (1,1) from our analysis. For $-1 < x < 0$, we have that f is constant with slope $s = -1$. Consequently, the derivative $f'(x) = -1$, for these x .

At $x = 0$, we observe that f is linear to the left with $f'(x) = -1$ and that it is also linear to the right, however, with $f'(x) = 1$, for $0 < x < 0.5$. So, at $x = 0$, $L^U = 1$ while $L^L = -1$. Since here $L^U \neq L^L$, the derivative of f does not exist at $x = 0$.

For $0 < x < 0.5$, we have the constant derivative $f'(x) = 1$. The corresponding slope of 1 through (0,0) and (0.5,0.5) is indicated by the dashed line. At $x = 0.5$, the left side limit $L^L = 1$ while the right side limit $L^U = 0.8776$. (This value of $\cos(0.5) = 0.8776$ is a result from calculus.) Hence, the two limits are not equal and, consequently, f is not differentiable at $x = 0.5$.

Without formal proof, we state that f is differentiable for all $0.5 < x < 2$. For example, at $x = 1$, $L^L = L^U = 0.5403$ and, thus, the derivative $f'(1) = 0.5403$. The dash-dotted line indicating this derivative is called the tangent of f at $x = 1$. In Figure 5, the arrow indexed $f'(1)$ points at this tangent. As another example, we select $x = 1.571$ where f assumes its maximum value. Here, the derivative $f'(1.571) = 0$ and, hence,

the tangent at $x = 1.571$ is flat as indicated by the horizontal dotted line. In Figure 5, the arrow indexed $f'(1.571)$ points at this tangent.

MONOTONIC FUNCTION

Suppose we have some function $f(x)$ for real-valued x . For example, the graph of f may look like that in Figure 7. We see that on the interval $[0,1]$, the graph is increasing from $f(0) = 0$ to $f(1) = 1$. For $1 \leq x \leq 2$, the graph remains at the level $f(1) = 1$ like a platform. And, finally, between $x = 2$ and $x = 3$, the graph is increasing, again, from $f(2) = 1$ to $f(3) = 2$.

In contrast, we may have another function, $g(x)$. Its graph is given by Figure 8. It looks somewhat similar to the graph in Figure 7, however, without the platform. The graph of g never remains at a level, but increases constantly. Even for the smallest increments from one value of x , say x_1 , to the next higher, say x_2 , there is always an upward slope in the graph.

Both functions, f and g , never decrease. The distinction is that f is *monotonically increasing* since the graph can remain at some level, while g is *strictly monotonic increasing* since its graph never remains at any level. If we can differentiate f and g , we can express this in terms of the derivatives of f and g . Let f' be the derivative of f and g' the derivative of g . Then, we have the following definitions of continuity for continuous functions with existing derivatives:

Monotonically increasing functions: A continuous function f with derivative f' is monotonically increasing if its derivative $f' \geq 0$.

Strictly monotonic increasing functions: A continuous function g with derivative g' is strictly monotonic increasing if its derivative $g' > 0$.

Analogously, a function $f(x)$ is monotonically decreasing if it behaves in the opposite manner. That is, f never increases when moving from some x to any higher value $x_1 > x$. When f is continuous with derivative f' , then we say that f is *monotonically decreasing* if $f'(x) \leq 0$ and that it is *strictly monotonic increasing* if $f'(x) < 0$ for all x . For these two cases, illustrations are given by

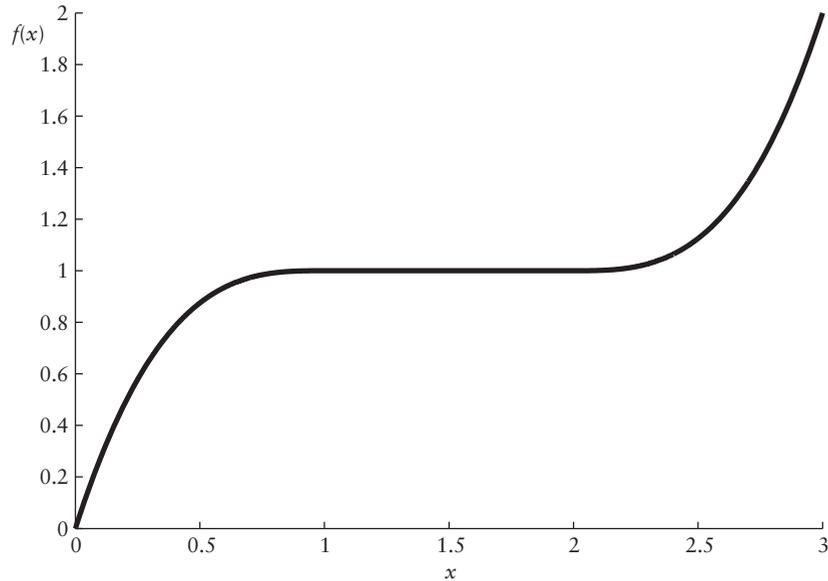

Figure 7 Monotonically Increasing Function f

mirroring the graphs in Figures 7 and 8 against their vertical axes, respectively.

INTEGRAL

Here we derive the concept of integration necessary to understand the probability density and continuous distribution function. The *integral*

of some function over some set of values represents the area between the function values and the horizontal axis. To sketch the idea, we start with an intuitive graphical illustration.

We begin by analyzing the area A between the graph (solid line) of the function $f(t)$ and the horizontal axis between $t = 0$ and $t = T$ in Figure 9. Looking at the graph, it appears

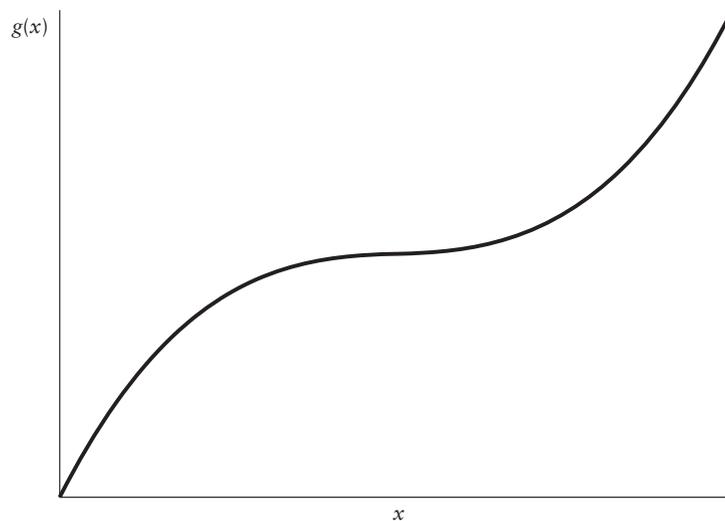

Figure 8 Strictly Monotonic Increasing Function g

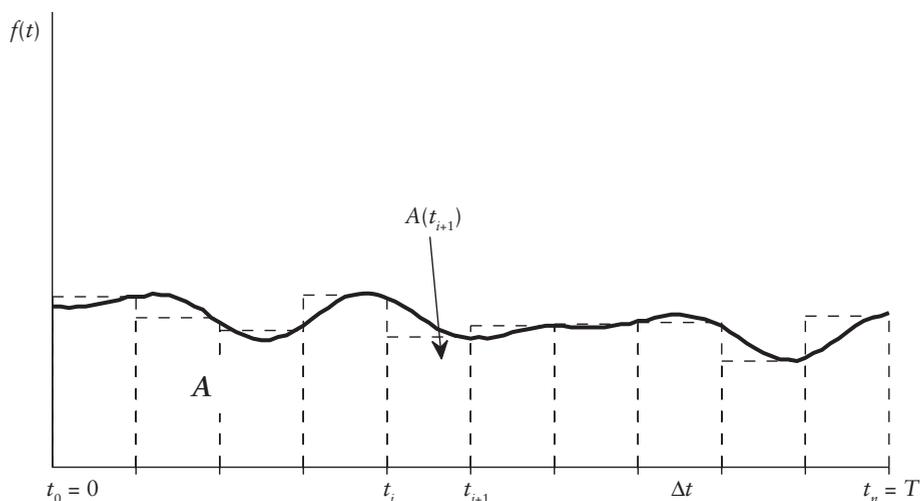

Figure 9 Approximation of the Area A between Graph of $f(t)$ and the Horizontal Axis, for $0 \leq t \leq T$

quite complicated to compute this area A in comparison to, for example, the area of a rectangle where we would only need to know its width and length. However, we can approximate this area by rectangles as will be done next.

Approximation of the Area through Rectangles

Let's approximate the area A under the function graph in Figure 9 as follows. As a first step, we dissect the interval between 0 and T into n equidistant intervals of length $\Delta t = t_{i+1} - t_i$ for $i = 0, 1, \dots, n - 1$. For each such interval, we consider the function value $f(t_{i+1})$ at the rightmost point, t_{i+1} . To obtain an estimate of the area under the graph for the respective interval, we multiply the value $f(t_{i+1})$ at t_{i+1} by the interval width Δt yielding $A(t_{i+1}) = \Delta t \cdot f(t_{i+1})$, which equals the area of the rectangle above interval $i + 1$ as displayed in Figure 9. Finally, we add up the areas $A(t_1), A(t_2), \dots, A(T)$ of all rectangles resulting in the desired estimate of the area A

$$\sum_{i=0}^{n-1} A(t_{i+1}) = \sum_{i=0}^{n-1} \Delta t \cdot f(t_{i+1}) \quad (4)$$

We repeat the just described procedure for decreasing interval widths Δt .

Integral as the Limiting Area

To derive the perfect approximation of the area under the curve in Figure 9, we let the interval width Δt gradually vanish until it almost equals 0, proceeding as before. We denote this infinitesimally small width by the step rate dt . Now, the difference between the function values at either end, that is, $f(t_i)$ and $f(t_{i+1})$, of the interval $i + 1$ will be nearly indistinguishable since t_i and t_{i+1} almost coincide. Hence, the corresponding rectangle with area $A(t_{i+1})$ will turn into a dash with infinitesimally small base dt .

Summation as in equation (4) of the areas of the dashes becomes infeasible. For this purpose, the *integral* has been introduced as the limit of (4) as $\Delta t \rightarrow 0$. (Conditions under which these limits exist are omitted here.) It is denoted by

$$\int_0^T f(t)dt \quad (5)$$

where the limits 0 and T indicate which interval the integration is performed on. In our case, the integration variable is t while the function $f(t)$ is called the integrand. In words, equation (5) is the integral of the function $f(t)$ over t from 0 to T . It is immaterial how we denote the integration variable. The same result as in equation (5)

would result if we wrote

$$\int_0^T f(y)dy$$

instead. The important factors are the integrand and the integral limits.

Note that instead of using the function values of the right boundaries of the intervals $f(t_{i+1})$ in equation (4), referred to as the right-point rule, we might as well have taken the function values of the left boundaries $f(t_i)$, referred to as the left-point rule, which would have led to the same integral. Moreover, we might have taken the function $f(0.5 \cdot (t_{i+1} + t_i))$ values evaluated at the mid-points of the intervals and still obtained the same interval. This latter procedure is called the mid-point rule.

If we keep 0 as the lower limit of the integral in equation (5) and vary T , then equation (5) becomes a function of the variable T . We may denote this function by

$$F(T) = \int_0^T f(t)dt \quad (6)$$

Relationship Between Integral and Derivative

In equation (6) the relationship between $f(t)$ and $F(T)$ is as follows. Suppose we compute the derivative of $F(T)$ with respect to T and assume that $F(T)$ is differentiable, for $T > 0$. The result is

$$F'(T) = \frac{dF(T)}{dT} = f(T) \quad (7)$$

Hence, from equation (7) we see that the marginal increment of the integral at any point (i.e., its derivative) is exactly equal to the integrand evaluated at the according value. This need not generally be true. But in most cases, particularly in financial modeling, this statement is valid.

The implication of this discussion for probability theory is as follows. Let P be a continuous probability measure with probability distribu-

tion function F and (probability) density function f . There is the unique link between f and P given through

$$P(X \leq x) = F(x) = \int_{-\infty}^{\infty} f(x)dx \quad (8)$$

Formally, the integration of f over x is always from $-\infty$ to ∞ , even if the support is not on the entire real line. This is no problem, however, since the density is zero outside the support and, hence, integration over those parts yields 0 contribution to the integral. For example, suppose that some density function were

$$f(x) = \begin{cases} h(x), & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (9)$$

where $h(x)$ is just some function such that f satisfies the requirements for a density function. That is, the support is only on the positive part of the real line. Substituting the function from equation (9) into equation (8) yields the equality

$$\int_{-\infty}^{\infty} f(x)dx = \int_0^{\infty} f(x)dx = \int_0^{\infty} h(x)dx \quad (10)$$

SOME FUNCTIONS

Here we introduce some functions needed in probability theory to describe probability distributions of random variables: factorials, gamma function, beta function, Bessel function of the third kind, and characteristic function. While the first four are functions of very special shape, the characteristic function is of a more general structure. It is the function characterizing the probability distribution of some random variable and, hence, is of unique form for each random variable.

Factorial

Let $k \in \mathbf{N}$ (i.e., $k = 1, 2, \dots$). Then the *factorial* of this natural number k , denoted by the symbol $!$, is given by

$$k! = k \cdot (k - 1) \cdot (k - 2) \cdot \dots \cdot 1 \quad (11)$$

A factorial is the product of this number and all natural numbers smaller than k including 1. By definition, the factorial of zero is one (i.e., $0! \equiv 1$). For example, the factorial of 3 is $3! = 3 \cdot 2 \cdot 1 = 6$.

Gamma Function

The *gamma function* for nonnegative values x is defined by

$$\Gamma(x) = \int_0^{\infty} e^{-t} t^{x-1} dt, \quad x \geq 0 \quad (12)$$

The gamma function has the following properties. If the x correspond with a natural number $n \in N$ (i.e., $n = 1, 2, \dots$), then we have that equation (12) equals the factorial given by equation (11) of $n - 1$. Formally, this is

$$\Gamma(n) = (n - 1)! = (n - 1) \cdot (n - 2) \cdot \dots \cdot 1$$

Furthermore, for any $x \geq 0$, it holds that $\Gamma(x + 1) = x\Gamma(x)$.

In Figure 10, we have displayed part of the gamma function for x values between 0.1 and 5. Note that, for either $x \rightarrow 0$ or $x \rightarrow \infty$, $\Gamma(x)$ goes to infinity.

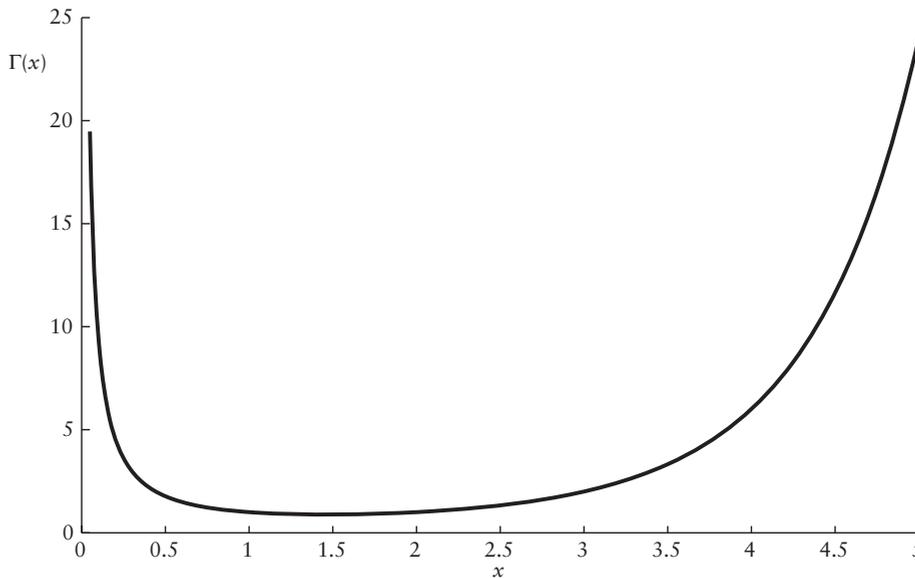

Figure 10 Gamma Function $\Gamma(x)$

Beta Function

The *beta function* with parameters c and d is defined as

$$B(c, d) = \int_0^1 u^{c-1} (1 - u)^{d-1} du = \frac{\Gamma(c)\Gamma(d)}{\Gamma(c + d)}$$

where Γ is the gamma function from equation (12).

Bessel Function of the Third Kind

The *Bessel function* of the third kind is defined as

$$K_1(x) = \frac{1}{2} \int_0^{\infty} \exp \left\{ -\frac{x}{2} \left(y + \frac{1}{y} \right) \right\} dy$$

This function is often a component of other, more complex functions such as the density function of the *NIG* distribution.

Characteristic Function

Before advancing to introduce the *characteristic function*, we briefly explain complex numbers.

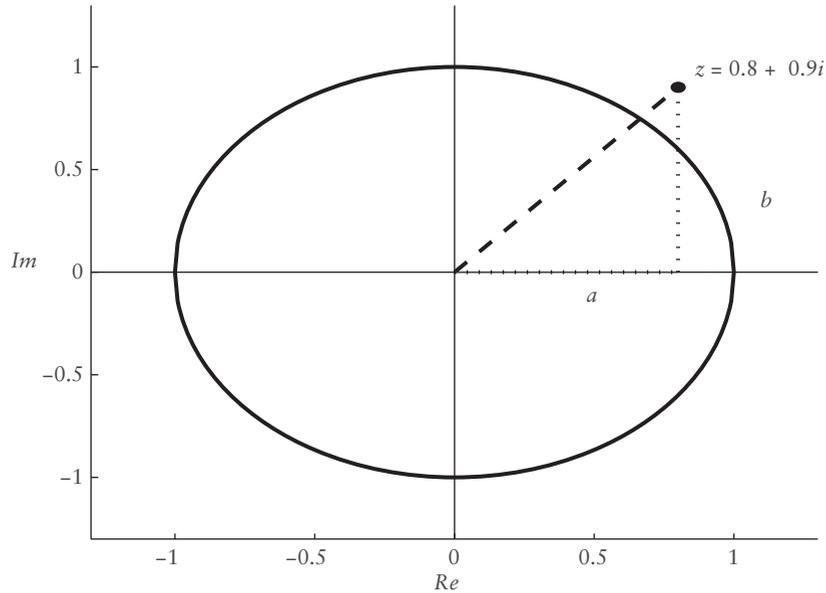

Figure 11 Graphical Representation of the Complex Number $z = 0.8 + 0.9i$

Suppose we were to take the square root of the number -1 , that is, $\sqrt{-1}$. So far, our calculus has no solution for this since the square root of negative numbers has not yet been introduced. However, by introducing the imaginary number i , which is defined as

$$i = \sqrt{-1}$$

we can solve square roots of any real number. Now, we can represent any number as the combination of a real (*Re*) part a plus some units b of i , which we refer to as the imaginary (*Im*) part. Then, any number z will look like

$$z = a + i \cdot b \quad (13)$$

The number given by equation (13) is a complex number. The set of complex numbers is symbolized by \mathbf{C} . This set contains the real numbers that are those complex numbers with $b = 0$. Graphically, we can represent the complex numbers on a two-dimensional space as given in Figure 11.

Now, we can introduce the characteristic function as some function ϕ mapping real numbers into the complex numbers. Formally, we write this as $\phi: \mathbf{R} \rightarrow \mathbf{C}$. Suppose we have some ran-

dom variable X with density function f . The characteristic function is then defined as

$$\phi(t) = \int_{-\infty}^{\infty} e^{itx} f(x) dx \quad (14)$$

which transforms the density f into some complex number at any real position t . Equation (14) is commonly referred to as the Fourier transformation of the density.

The relationship between the characteristic function ϕ and the density function f of some random variable is unique. So, when we state either one, the probability distribution of the corresponding random variable is unmistakably determined.

KEY POINTS

- Continuous functions are an integral component of mathematical analysis. They are useful whenever jumps in the function values are undesirable. This is often the case when financial asset returns are modeled; that is, one assumes that, in particular logarithmic returns, they may assume any value on the

real line such that the related probability distribution is continuous with continuous probability density.

- The indicator function is defined as a function yielding one for certain specified argument values and zero in any other case. It is helpful in expressing so-called exclusive either-or behavior of random variables (i.e., when random variables can only assume exactly one of two values). For example, when one models call option prices where, at maturity, the value of the option is equal to either zero or the difference between the market value of the underlying and the strike price, one resorts to the indicator function.
- The derivative of some function expresses the function's rate of growth at some point for infinitesimally small increments. In words, it expresses by how much the function changes if one takes a very small step. In probability theory, a derivative is used in the context of a continuous probability distribution to express by how much the distribution function increases at a certain value (i.e., the marginal rate of probability at a certain value).
- The integral is the continuous analogue of the sum of discrete values. In probability theory, the probability of individual outcomes is always zero when the distribution is continu-

ous. In order to express the probability of at most a certain value, we cannot sum the individual probabilities of all values less than or equal to the critical value. Instead, at each value, we have the density function which we integrate up to the critical value, yielding the requested probability.

- The characteristic function is the unique representation of a probability distribution. For certain distributions, the probability density function or the distribution function are unknown. Instead, it is necessary to resort to the characteristic function. Technically, the characteristic function is a function involving complex numbers (i.e., numbers including the square root of minus one) to express the behavior of some function at certain frequencies. It is closely linked to the Fourier transform used in engineering.

Time Value of Money

PAMELA P. DRAKE, PhD, CFA

J. Gray Ferguson Professor of Finance, College of Business, James Madison University

FRANK J. FABOZZI, PhD, CFA, CPA

Professor of Finance, EDHEC Business School

Abstract: Investing decisions require the valuation of investments and the determination of yields on investments. Necessary for the valuation and yield determination are the financial mathematics that involve the time value of money. With these mathematics, future cash flows can be translated to a value in the present, a value today can be converted into a value at some future point in time, and the yield on an investment can be computed.

In this entry, we introduce the mathematical process of translating a value today into a value at some future point in time, and then show how this process can be reversed to determine the value today of some future amount. We then show how to extend the time value of money mathematics to include multiple cash flows and the special cases of annuities and loan amortization. Finally, we demonstrate how these mathematics can be used to calculate the yield on an investment.¹

IMPORTANCE OF THE TIME VALUE OF MONEY

The notion that money has a time value is one of the most basic concepts in investment analysis. Making decisions today regarding future cash flows requires understanding that the value of money does not remain the same throughout time.

A dollar today is worth less than a dollar some time in the future for two reasons:

Reason 1: Cash flows occurring at different points in time have different values relative to any one point in time.

One dollar one year from now is not as valuable as one dollar today. After all, you can invest a dollar today and earn interest so that the value it grows to next year is greater than the one dollar today. This means we have to take into account the *time value of money* to quantify the relation between cash flows at different points in time.

Reason 2: Cash flows are uncertain.

Expected cash flows may not materialize. Uncertainty stems from the nature of forecasts of the timing and/or the amount of cash flows. We do not know for certain when, whether, or how much cash flows will be in the future. This uncertainty regarding future cash flows must somehow be taken

into account in assessing the value of an investment.

Translating a current value into its equivalent future value is referred to as compounding. Translating a future cash flow or value into its equivalent value in a prior period is referred to as discounting. This entry outlines the basic mathematical techniques used in compounding and discounting.

Suppose someone wants to borrow \$100 today and promises to pay back the amount borrowed in one month. Would the repayment of only the \$100 be fair? Probably not. There are two things to consider. First, if the lender didn't lend the \$100, what could he or she have done with it? Second, is there a chance that the borrower may not pay back the loan? So, when considering lending money, we must consider the opportunity cost (that is, what could have been earned or enjoyed), as well as the uncertainty associated with getting the money back as promised.

Let's say that someone is willing to lend the money, but that they require repayment of the \$100 plus some compensation for the opportunity cost and any uncertainty the loan will be repaid as promised. The amount of the loan, the \$100, is the principal. The compensation required for allowing someone else to use the \$100 is the interest.

Looking at this same situation from the perspective of time and value, the amount that you are willing to lend today is the loan's present value. The amount that you require to be paid at the end of the loan period is the loan's future value. Therefore, the future period's value is comprised of two parts:

$$\text{Future value} = \text{Present value} + \text{Interest}$$

The interest is compensation for the use of funds for a specific period. It consists of (1) compensation for the length of time the money is borrowed and (2) compensation for the risk that the amount borrowed will not be repaid exactly as set forth in the loan agreement.

DETERMINING THE FUTURE VALUE

Suppose you deposit \$1,000 into a savings account at the Surety Savings Bank and you are promised 10% interest per period. At the end of one period you would have \$1,100. This \$1,100 consists of the return of your principal amount of the investment (the \$1,000) and the interest or return on your investment (the \$100). Let's label these values:

- \$1,000 is the value today, the present value, PV .
- \$1,100 is the value at the end of one period, the future value, FV .
- 10% is the rate interest is earned in one period, the interest rate, i .

To get to the future value from the present value:

$$FV = \underset{\substack{\uparrow \\ \text{principal}}}{PV} + (PV \times \underset{\substack{\uparrow \\ \text{interest}}}{i})$$

This is equivalent to:

$$FV = PV(1 + i)$$

In terms of our example,

$$\begin{aligned} FV &= \$1,000 + (\$1,000 \times 0.10) \\ &= \$1,000(1 + 0.10) = \$1,100 \end{aligned}$$

If the \$100 interest is withdrawn at the end of the period, the principal is left to earn interest at the 10% rate. Whenever you do this, you earn *simple interest*. It is simple because it repeats itself in exactly the same way from one period to the next as long as you take out the interest at the end of each period and the principal remains the same. If, on the other hand, both the principal and the interest are left on deposit at the Surety Savings Bank, the balance earns interest on the previously paid interest, referred to as *compound interest*. Earning interest on interest is called compounding because the balance at any time is a combination of the principal, interest on principal, and *interest on accumulated interest* (or simply, *interest on interest*).

If you compound interest for one more period in our example, the original \$1,000 grows to \$1,210.00:

$$\begin{aligned}
 FV &= \text{Principal} + \text{First period interest} \\
 &\quad + \text{Second period interest} \\
 &= \$1,000.00 + (\$1,000.00 \times 0.10) \\
 &\quad + (\$1,100.00 \times 0.10) \\
 &= \$1,200.00
 \end{aligned}$$

The present value of the investment is \$1,000, the interest earned over two years is \$210, and the future value of the investment after two years is \$1,210.

The relation between the present value and the future value after two periods, breaking out the second period interest into interest on the principal and interest on interest, is:

$$\begin{aligned}
 FV &= \underset{\substack{\uparrow \\ \text{Principal}}}{PV} + \underset{\substack{\uparrow \\ \text{First} \\ \text{period's} \\ \text{interest on} \\ \text{the principal}}}{(PV \times i)} + \underset{\substack{\uparrow \\ \text{Second} \\ \text{period's} \\ \text{interest on} \\ \text{the principal}}}{(PV \times i)} + \underset{\substack{\uparrow \\ \text{Second} \\ \text{period's} \\ \text{interest on} \\ \text{the first} \\ \text{period's} \\ \text{interest}}}{(PV \times i \times i)}
 \end{aligned}$$

or, collecting the PVs from each term and applying a bit of elementary algebra,

$$FV = PV(1 + 2i + i^2) = PV(1 + i)^2$$

The balance in the account two years from now, \$1,210, comprises three parts:

1. The principal, \$1,000.
2. Interest on principal, \$100 in the first period plus \$100 in the second period.
3. Interest on interest, 10% of the first period's interest, or \$10.

To determine the future value with compound interest for more than two periods, we follow along the same lines:

$$FV = PV(1 + i)^N \tag{1}$$

The value of N is the number of compounding periods, where a compounding period is the unit of time after which interest is paid at the rate i . A period may be any length of time: a minute, a day, a month, or a year. The important thing is to make sure the same compound-

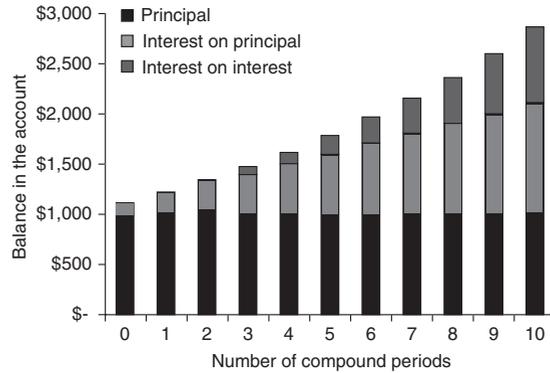

Figure 1 The Value of \$1,000 Invested 10 Years in an Account That Pays 10% Compounded Interest per Year

ing period is reflected throughout the problem being analyzed. The term “ $(1 + i)^N$ ” is referred to as the compound factor. It is the rate of exchange between present dollars and dollars N compounding periods into the future. Equation (1) is the basic valuation equation—the foundation of financial mathematics. It relates a value at one point in time to a value at another point in time, considering the compounding of interest.

The relation between present and future values for a principal of \$1,000 and interest of 10% per period through 10 compounding periods is shown graphically in Figure 1. For example, the value of \$1,000, earning interest at 10% per period, is \$2,593.70 ten periods into the future:

$$\begin{aligned}
 FV &= \$1,000 (1 + 0.10)^{10} = \$1,000 (2.5937) \\
 &= \$2,593.70
 \end{aligned}$$

As you can see in this figure the \$2,593.70 balance in the account at the end of 10 periods is comprised of three parts:

1. The principal, \$1,000.
2. Interest on the principal of \$1,000, which is \$100 per period for 10 periods or \$1,000.
3. Interest on interest totaling \$593.70.

We can express the change in the value of the savings balance (that is, the difference between the ending value and the beginning value) as a growth rate. A *growth rate* is the rate at which a value appreciates (a positive growth) or

depreciates (a negative growth) over time. Our \$1,000 grew at a rate of 10% per year over the 10-year period to \$2,593.70. The average annual growth rate of our investment of \$1,000 is 10%—the value of the savings account balance increased 10% per year.

We could also express the appreciation in our savings balance in terms of a return. A *return* is the income on an investment, generally stated as a change in the value of the investment over each period divided by the amount at the investment at the beginning of the period. We could also say that our investment of \$1,000 provides an average annual return of 10% per year. The average annual return is not calculated by taking the change in value over the entire 10-year period ($\$2,593.70 - \$1,000$) and dividing it by \$1,000. This would produce an *arithmetic average return* of 159.37% over the 10-year period, or 15.937% per year. But the arithmetic average ignores the process of compounding. The correct way of calculating the average annual return is to use a *geometric average return*:

$$i = \sqrt[N]{\frac{FV}{PV}} - 1 \quad (2)$$

which is a rearrangement of equation (1) Using the values from the example,

$$i = \sqrt[10]{\frac{\$2,593.70}{\$1,000.00}} - 1 = \left(\frac{\$2,593.70}{\$1,000.00}\right)^{1/10} - 1 = 1.100 - 1 = 10\%$$

Therefore, the annual return on the investment—sometimes referred to as the *compound average annual return* or the *true return*—is 10% per year.

Here is another example for calculating a future value. A common investment product of a life insurance company is a guaranteed investment contract (GIC). With this investment, an insurance company guarantees a specified interest rate for a period of years. Suppose that the life insurance company agrees to pay 6% annually for a five-year GIC and the amount invested by the policyholder is \$10 million. The amount of the liability (that is, the amount this

life insurance company has agreed to pay the GIC policyholder) is the future value of \$10 million when invested at 6% interest for five years. In terms of equation (1), $PV = \$10,000,000$, $i = 6\%$, and $N = 5$, so that the future value is:

$$FV = \$10,000,000 (1 + 0.06)^5 = \$13,382,256$$

Compounding More Than One Time per Year

An investment may pay interest more than one time per year. For example, interest may be paid semiannually, quarterly, monthly, weekly, or daily, even though the stated rate is quoted on an annual basis. If the interest is stated as, say, 10% per year, compounded semiannually, the nominal rate—often referred to as the *annual percentage rate* (APR)—is 10%. The basic valuation equation handles situations in which there is compounding more frequently than once a year if we translate the nominal rate into a rate per compounding period. Therefore, an APR of 10% with compounding semiannually is 5% per period—where a period is six months—and the number of periods in one year is 2.

Consider a deposit of \$50,000 in an account for five years that pays 8% interest, compounded quarterly. The interest rate per period, i , is $8\%/4 = 2\%$ and the number of compounding periods is $5 \times 4 = 20$. Therefore, the balance in the account at the end of five years is:

$$FV = \$50,000(1 + 0.02)^{20} = \$50,000(1.4859474) = \$74,297.37$$

As shown in Figure 2, through 50 years with both annual and quarterly compounding, the investment's value increases at a faster rate with the increased frequency of compounding.

The last example illustrates the need to correctly identify the “period” because this dictates the interest rate per period and the number of compounding periods. Because interest rates are often quoted in terms of an APR, we need to be able to translate the APR into an interest rate per period and to adjust the number of

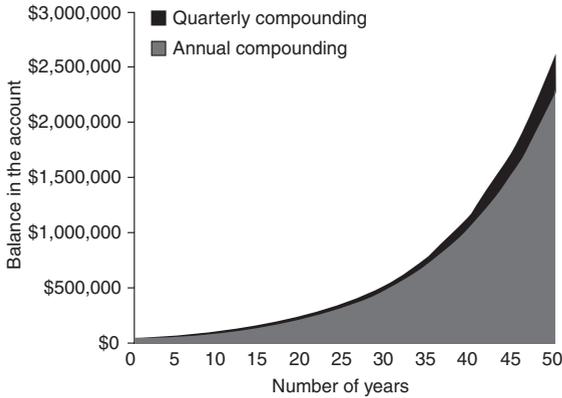

Figure 2 Value of \$50,000 Invested in the Account that Pays 8% Interest per Year: Quarterly versus Annual Compounding

periods. To see how this works, let’s use an example of a deposit of \$1,000 in an account that pays interest at a rate of 12% per year, with interest compounded for different compounding frequencies. How much is in the account after, say, five years depends on the compounding frequency:

Com- pounding Frequency	Period	Rate per Compound- ing Period, i	Number of Periods in Five Years, N	FV at the End of Five Years
Annual	One year	12%	5	\$1,762.34
Semiannual	Six months	6%	10	1,790.85
Quarterly	Three months	3%	20	1,806.11
Monthly	One month	1%	60	1,816.70

As you can see, both the rate per period, i , and the number of compounding periods, N , are adjusted and depend on the frequency of compounding. Interest can be compounded for any frequency, such as daily or hourly.

Let’s work through another example for compounding with compounding more than once a year. Suppose we invest \$200,000 in an investment that pays 4% interest per year, compounded quarterly. What will be the future value of this investment at the end of 10 years?

The given information is $i = 4\%/4 = 1\%$ and $N = 10 \times 4 = 40$ quarters. Therefore,

$$FV = \$200,000(1 + 0.01)^{40} = \$297,772.75$$

Continuous Compounding

The extreme frequency of compounding is *continuous compounding*—interest is compounded instantaneously. The factor for compounding continuously for one year is e^{APR} , where e is 2.71828 . . . , the base of the natural logarithm. And the factor for compounding continuously for two years is $e^{APR} e^{APR}$ or e^{2APR} . The future value of an amount that is compounded continuously for N years is:

$$FV = PVe^{N(APR)} \tag{3}$$

where APR is the annual percentage rate and $e^{N(APR)}$ is the compound factor.

If \$1,000 is deposited in an account for five years with interest of 12% per year, compounded continuously,

$$\begin{aligned} FV &= \$1,000e^{5(0.12)} = \$1,000(e^{0.60}) \\ &= \$1,000(1.82212) = \$1,822.12 \end{aligned}$$

Comparing this future value with that if interest is compounded annually at 12% per year for five years, \$1,762.34, we see the effects of this extreme frequency of compounding.

Multiple Rates

In our discussion thus far, we have assumed that the investment will earn the same periodic interest rate, i . We can extend the calculation of a future value to allow for different interest rates or growth rates for different periods. Suppose an investment of \$10,000 pays 9% during the first year and 10% during the second year. At the end of the first period, the value of the investment is \$10,000 $(1 + 0.09)$, or \$10,900. During the second period, this \$10,900 earns interest at 10%. Therefore, the future value of this \$10,000 at the end of the second period is:

$$FV = \$10,000(1 + 0.09)(1 + 0.10) = \$11,990$$

We can write this more generally as:

$$FV = PV(1 + i_1)(1 + i_2)(1 + i_3) \dots (1 + i_N) \tag{4}$$

where i_N is the interest rate for period N .

Consider a \$50,000 investment in a one-year bank certificate of deposit (CD) today and rolled over annually for the next two years into one-year CDs. The future value of the \$50,000 investment will depend on the one-year CD rate each time the funds are rolled over. Assuming that the one-year CD rate today is 5% and that it is expected that the one-year CD rate one year from now will be 6%, and the one-year CD rate two years from now will be 6.5%, then we know:

$$\begin{aligned} FV &= \$50,000(1 + 0.05)(1 + 0.06)(1 + 0.065) \\ &= \$59,267.25 \end{aligned}$$

Continuing this example, what is the average annual interest rate over this period? We know that the future value is \$59,267.25, the present value is \$50,000, and $N = 3$:

$$i = \sqrt[3]{\frac{\$59,267.25}{\$50,000.00}} - 1 = \sqrt[3]{1.185345} - 1 = 5.8315\%$$

which is also:

$$\begin{aligned} i &= \sqrt[3]{(1 + 0.05) + (1 + 0.06)(1 + 0.065)} - 1 \\ &= 5.8315\% \end{aligned}$$

DETERMINING THE PRESENT VALUE

Now that we understand how to compute future values, let's work the process in reverse. Suppose that for borrowing a specific amount of money today, the Yenom Company promises to pay lenders \$5,000 two years from today. How much should the lenders be willing to lend Yenom in exchange for this promise? This dilemma is different than figuring out a future value. Here we are given the future value and have to figure out the present value. But we can use the same basic idea from the future value problems to solve present value problems.

If you can earn 10% on other investments that have the same amount of uncertainty as the \$5,000 Yenom promises to pay, then:

- The future value, $FV = \$5,000$.
- The number of compounding periods, $N = 2$.
- The interest rate, $i = 10\%$.

We also know the basic relation between the present and future values:

$$FV = PV(1 + i)^N$$

Substituting the known values into this equation:

$$\$5,000 = PV(1 + 0.10)^2$$

To determine how much you are willing to lend now, PV , to get \$5,000 one year from now, FV , requires solving this equation for the unknown present value:

$$\begin{aligned} PV &= \frac{\$5,000}{(1 + 0.10)^2} = \$5,000 \left(\frac{1}{1 + 0.10} \right)^2 \\ &= \$5,000(0.82645) = \$4,132.25 \end{aligned}$$

Therefore, you would be willing to lend \$4,132.25 to receive \$5,000 one year from today if your opportunity cost is 10%. We can check our work by reworking the problem from the reverse perspective. Suppose you invested \$4,132.25 for two years and it earned 10% per year. What is the value of this investment at the end of the year?

We know: $PV = \$4,132.25$, $N = 10\%$ or 0.10, and $i = 2$.

Therefore, the future value is:

$$\begin{aligned} FV &= PV(1 + i)^N = \$4,132.25 (1 + 0.10)^2 \\ &= \$5,000.00 \end{aligned}$$

Compounding translates a value in one point in time into a value at some future point in time. The opposite process translates future values into present values: Discounting translates a value back in time. From the basic valuation equation:

$$FV = PV(1 + i)^N$$

we divide both sides by $(1 + i)^N$ and exchange sides to get the present value,

$$PV = \frac{FV}{(1 + i)^N} \quad (5)$$

$$\text{or } PV = FV \left(\frac{1}{1 + i} \right)^N \quad \text{or } PV = FV \left[\frac{1}{(1 + i)^N} \right]$$

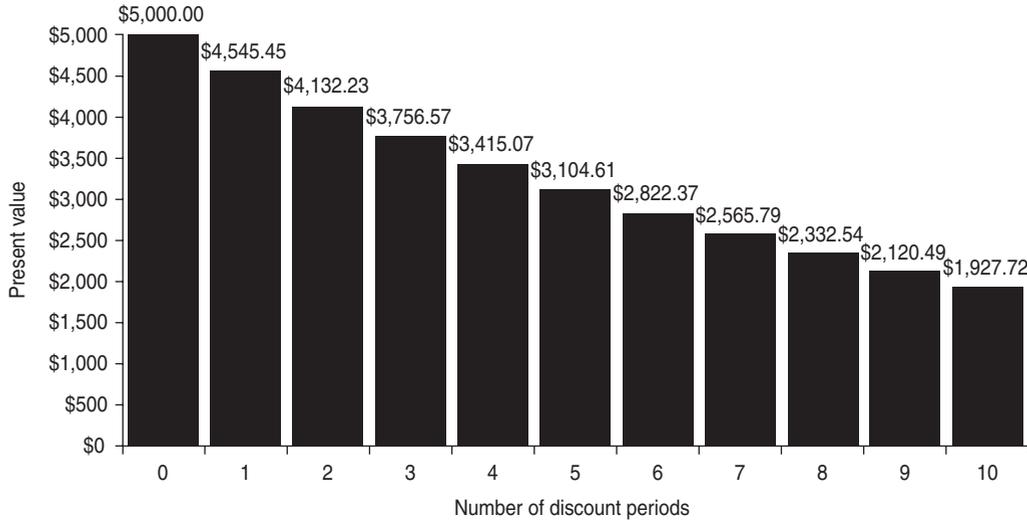

Figure 3 Present Value of \$5,000 Discounted at 10%

The term in brackets [] is referred to as the *discount factor* since it is used to translate a future value to its equivalent present value. The present value of \$5,000 for discount periods ranging from 0 to 10 is shown in Figure 3.

If the frequency of compounding is greater than once a year, we make adjustments to the rate per period and the number of periods as we did in compounding. For example, if the future value five years from today is \$100,000 and the interest is 6% per year, compounded semiannually, $i = 6\%/2 = 3\%$ and $N = 5 \times 2 = 10$, and the present value is:

$$PV = \$100,000(1 + 0.03)^{10} = \$100,000(1.34392) = \$134,392$$

Here is an example of calculating a present value. Suppose that the goal is to have \$75,000 in an account by the end of four years. And suppose that interest on this account is paid at a rate of 5% per year, compounded semiannually. How much must be deposited in the account today to reach this goal? We are given $FV = \$75,000$, $i = 5\%/2 = 2.5\%$ per six months, and $N = 4 \times 2 = 8$ six-month periods. The amount of the required deposit is therefore:

$$PV = \frac{\$75,000}{(1 + 0.025)^8} = \$61,555.99$$

DETERMINING THE UNKNOWN INTEREST RATE

As we saw earlier in our discussion of growth rates, we can rearrange the basic equation to solve for i :

$$i = \sqrt[N]{\frac{FV}{PV}} - 1 = \left(\frac{FV}{PV}\right)^{1/N} - 1$$

As an example, suppose that the value of an investment today is \$100 and the expected value of the investment in five years is expected to be \$150. What is the annual rate of appreciation in value of this investment over the five-year period?

$$i = \sqrt[5]{\frac{\$150}{\$100}} - 1 = \sqrt[5]{1.5} - 1 = 0.0845 \text{ or } 8.45\% \text{ per year}$$

There are many applications in finance where it is necessary to determine the rate of change in values over a period of time. If values are increasing over time, we refer to the rate of change as the growth rate. To make comparisons easier, we usually specify the growth rate as a rate per year.

For example, if we wish to determine the rate of growth in these values, we solve for the unknown interest rate. Consider the growth rate of

dividends for General Electric. General Electric pays dividends each year. In 1996, for example, General Electric paid dividends of \$0.317 per share of its common stock, whereas in 2006 the company paid \$1.03 in dividends per share. This represents a growth rate of 12.507%:

$$\begin{aligned}\text{Growth rate of dividends} &= \sqrt[10]{\frac{\$1.03}{\$0.317}} - 1 \\ &= \sqrt[10]{3.2492} - 1 \\ &= 12.507\%\end{aligned}$$

The 12.507% is the average annual rate of the growth during this 10-year span.

DETERMINING THE NUMBER OF COMPOUNDING PERIODS

Given the present and future values, calculating the number of periods when we know the interest rate is a bit more complex than calculating the interest rate when we know the number of periods. Nevertheless, we can develop an equation for determining the number of periods, beginning with the valuation formula given by equation (1) and rearranging to solve for N ,

$$N = \frac{\ln FV - \ln PV}{\ln(1 + i)} \quad (6)$$

where \ln indicates the natural logarithm, which is the log of the base e . (e is approximately equal to 2.718. The natural logarithm function can be found on most calculators, usually indicated by “ \ln ”.)

Suppose that the present value of an investment is \$100 and you wish to determine how long it will take for the investment to double in value if the investment earns 6% per year, compounded annually:

$$\begin{aligned}N &= \frac{\ln 200 - \ln 100}{\ln 1.06} = \frac{5.2983 - 4.6052}{0.0583} \\ &= 11.8885 \text{ or approximately } 12 \text{ years}\end{aligned}$$

You’ll notice that we round off to the next whole period. To see why, consider this last example. After 11.8885 years, we have doubled our money if interest were paid 88.85% the way through the 12th year. But, we stated earlier that interest is paid at the end of each period—not part of the way through. At the end of the 11th year, our investment is worth \$189.93, and at the end of the 12th year, our investment is worth \$201.22. So, our investment’s value doubles by the 12th period—with a little extra, \$1.22.

THE TIME VALUE OF A SERIES OF CASH FLOWS

Applications in finance may require the determination of the present or future value of a series of cash flows rather than simply a single cash flow. The principles of determining the future value or present value of a series of cash flows are the same as for a single cash flow, yet the math becomes a bit more cumbersome.

Suppose that the following deposits are made in a Thrifty Savings and Loan account paying 5% interest, compounded annually:

Time When Deposit Is Made	Amount of Deposit
Today	\$1,000
At the end of the first year	2,000
At the end of the second year	1,500

What is the balance in the savings account at the end of the second year if no withdrawals are made and interest is paid annually?

Let’s simplify any problem like this by referring to today as the end of period 0, and identifying the end of the first and each successive period as 1, 2, 3, and so on. Represent each end-of-period cash flow as “ CF ” with a subscript specifying the period to which it corresponds. Thus, CF_0 is a cash flow today, CF_{10} is a cash flow at the end of period 10, and CF_{25} is a cash flow at the end of period 25, and so on.

Representing the information in our example using cash flow and period notation:

Period	Cash Flow	End-of-Period Cash Flow
0	CF_0	\$1,000
1	CF_1	\$2,000
2	CF_2	\$1,500

The future value of the series of cash flows at the end of the second period is calculated as follows:

Period	End-of-Period Cash Flow	Number of Periods Interest Is Earned	Compounding Factor	Future Value
0	\$1,000	2	1.1025	\$1,102.50
1	2,000	1	1.0500	2,100.00
2	1,500	0	1.0000	1,500.00
				\$4,702.50

The last cash flow, \$1,500, was deposited at the very end of the second period—the point of time at which we wish to know the future value of the series. Therefore, this deposit earns no interest. In more formal terms, its future value is precisely equal to its present value.

Today, the end of period 0, the balance in the account is \$1,000 since the first deposit is made but no interest has been earned. At the end of period 1, the balance in the account is \$3,050, made up of three parts:

1. The first deposit, \$1,000.
2. \$50 interest on the first deposit.
3. The second deposit, \$2,000.

The balance in the account at the end of period 2 is \$4,702.50, made up of five parts:

1. The first deposit, \$1,000.
2. The second deposit, \$2,000.
3. The third deposit, \$1,500.
4. \$102.50 interest on the first deposit, \$50 earned at the end of the first period, \$52.50 more earned at the end of the second period.
5. \$100 interest earned on the second deposit at the end of the second period.

These cash flows can also be represented in a time line. A time line is used to help graph-

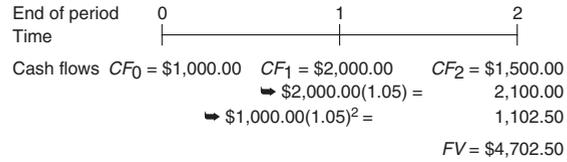

Figure 4 Time Line for the Future Value of a Series of Uneven Cash Flows Deposited to Earn 5% Compounded Interest per Period

ically depict and sort out each cash flow in a series. The time line for this example is shown in Figure 4. From this example, you can see that the future value of the entire series is the sum of each of the compounded cash flows comprising the series. In much the same way, we can determine the future value of a series comprising any number of cash flows. And if we need to, we can determine the future value of a number of cash flows before the end of the series.

For example, suppose you are planning to deposit \$1,000 today and at the end of each year for the next ten years in a savings account paying 5% interest annually. If you want to know the future value of this series after four years, you compound each cash flow for the number of years it takes to reach four years. That is, you compound the first cash flow over four years, the second cash flow over three years, the third over two years, the fourth over one year, and the fifth you don't compound at all because you will have just deposited it in the bank at the end of the fourth year.

To determine the present value of a series of future cash flows, each cash flow is discounted back to the present, where the beginning of the first period, today, is designated as 0. As an example, consider the Thrifty Savings & Loan problem from a different angle. Instead of calculating what the deposits and the interest on these deposits will be worth in the future, let's calculate the present value of the deposits. The present value is what these future deposits are worth today.

In the series of cash flows of \$1,000 today, \$2,000 at the end of period 1, and \$1,500 at

the end of period 2, each are discounted to the present, 0, as follows:

Period	End-of-Period Cash Flow	Number of Periods of Discounting	Discount Factor	Present Value
0	\$1,000	0	1.00000	\$1,000.00
1	\$2,000	1	0.95238	1,904.76
2	\$1,500	2	0.90703	1,360.54
				$FV = \$4,265.30$

The present value of the series is the sum of the present value of these three cash flows, \$4,265.30. For example, the \$1,500 cash flow at the end of period 2 is worth \$1,428.57 at the end of the first period and is worth \$1,360.54 today.

The present value of a series of cash flows can be represented in notation form as:

$$PV = CF_0 \left(\frac{1}{1+i} \right)^0 + CF_1 \left(\frac{1}{1+i} \right)^1 + CF_2 \left(\frac{1}{1+i} \right)^2 + \cdots + CF_N \left(\frac{1}{1+i} \right)^N$$

For example, if there are cash flows today and at the end of periods 1 and 2, today's cash flow is not discounted, the first period cash flow is discounted one period, and the second period cash flow is discounted two periods.

We can represent the present value of a series using summation notation as shown below:

$$PV = \sum_{t=0}^N CF_t \left(\frac{1}{1+i} \right)^t \quad (7)$$

This equation tells us that the present value of a series of cash flows is the sum of the products of each cash flow and its corresponding discount factor.

Shortcuts: Annuities

There are valuation problems that require us to evaluate a series of level cash flows—each cash flow is the same amount as the others—received at regular intervals. Let's suppose you expect to deposit \$2,000 at the end of each of the next four years in an account earning 8% compounded

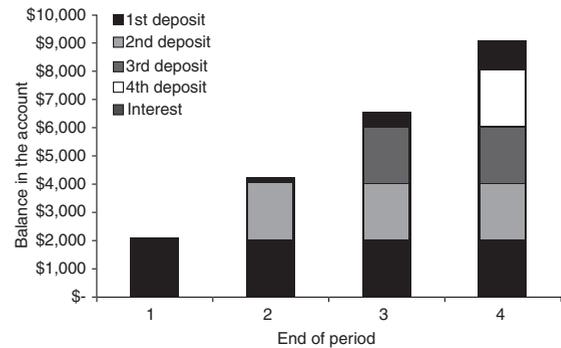

Figure 5 Balance in an Account in Which Deposits of \$2,000 Each Are Made Each Year (The Balance in the Account Earns 8%)

interest. How much will you have available at the end of the fourth year?

As we just did for the future value of a series of uneven cash flows, we can calculate the future value (as of the end of the fourth year) of each \$2,000 deposit, compounding interest at 8%:

$$\begin{aligned} FV &= \$2,000(1 + 0.08)^3 + \$2,000(1 + 0.08)^2 \\ &\quad + \$2,000(1 + 0.08)^1 + \$2,000(1 + 0.08)^0 \\ &= \$2,519.40 + \$2,332.80 + \$2,160.00 \\ &\quad + \$2,000 = \$9,012.20 \end{aligned}$$

Figure 5 shows the contribution of each deposit and the accumulated interest at the end of each period.

- At the end of the first year, there is \$2,000.00 in the account because you have just made your first deposit.
- At the end of the second, there is \$4,160.00 in the account: two deposits of \$2,000 each, plus \$160 interest (8% of \$2,000).
- At the end of the third year, there is \$6,492.80 in the account: three deposits of \$2,000.00 each, plus accumulated interest of \$492.80 [$\$160.00 + (0.08 \times \$4,000) + (0.08 \times \$160)$].
- At the end of the fourth year, you would have \$9,012.20 available: four deposits of \$2,000 each, plus \$1,012.20 accumulated interest [$\$160.00 + \$492.80 + (0.08 \times \$6,000) + (0.08 \times (\$160.00 + 492.80))$].

Notice that in our calculations, each deposit of \$2,000 is multiplied by a factor that corresponds to an interest rate of 8% and the number of periods that the deposit has been in the savings account. Since the deposit of \$2,000 is common to each multiplication, we can simplify the math a bit by multiplying the \$2,000 by the sum of the factors to get the same answer:

$$\begin{aligned} FV &= \$2,000(1.2597) + \$2,000(1.1664) \\ &\quad + \$2,000(1.0800) + \$2,000(1.0000) \\ &= \$9,012.20 \end{aligned}$$

A series of cash flows of equal amount occurring at even intervals is referred to as an annuity. Determining the value of an annuity, whether compounding or discounting, is simpler than valuing uneven cash flows. If each CF_t is equal (that is, all the cash flows are the same value) and the first one occurs at the end of the first period ($t = 1$), we can express the future value of the series as:

$$FV = \sum_{t=1}^N CF_t(1+i)^{N-t}$$

N is last and t indicates the time period corresponding to a particular cash flow, starting at 1 for an ordinary annuity. Since CF_t is shorthand for: $CF_1, CF_2, CF_3, \dots, CF_N$, and we know that $CF_1 = CF_2 = CF_3 = \dots = CF_N$, let's make things simple by using CF to indicate the same value for the periodic cash flows. Rearranging the future value equation we get:

$$FV = CF \sum_{t=1}^N (1+i)^{N-t} \tag{8}$$

This equation tells us that the future value of a level series of cash flows, occurring at regular intervals beginning one period from today (notice that t starts at 1), is equal to the amount of cash flow multiplied by the sum of the compound factors.

In a like manner, the equation for the present value of a series of level cash flows beginning

after one period simplifies to:

$$PV = \sum_{t=1}^N CF_t \left(\frac{1}{1+i} \right)^t = CF \sum_{t=1}^N \left(\frac{1}{1+i} \right)^t$$

or

$$PV = CF \sum_{t=1}^N \frac{1}{(1+i)^t} \tag{9}$$

This equation tells us that the present value of an annuity is equal to the amount of one cash flow multiplied by the sum of the discount factors.

Equations (8) and (9) are the valuation—future and present value—formulas for an *ordinary annuity*. An ordinary annuity is a special form of annuity, where the first cash flow occurs at the end of the first period.

To calculate the future value of an annuity we multiply the amount of the annuity (that is, the amount of one periodic cash flow) by the sum of the compound factors. The sum of these compounding factors for a given interest rate, i , and number of periods, N , is referred to as the *future value annuity factor*. Likewise, to calculate the present value of an annuity we multiply one cash flow of the annuity by the sum of the discount factors. The sum of the discounting factors for a given i and N is referred to as the *present value annuity factor*.

Suppose you wish to determine the future value of a series of deposits of \$1,000, deposited each year in the No Fault Vault Bank for five years, with the first deposit made at the end of the first year. If the NFV Bank pays 5% interest on the balance in the account at the end of each year and no withdrawals are made, what is the balance in the account at the end of the five years?

Each \$1,000 is deposited at a different time, so it contributes a different amount to the future value. For example, the first deposit accumulates interest for four periods, contributing \$1,215.50 to the future value (at the end of period 5), whereas the last deposit contributes only \$1,000 to the future value since it is deposited at exactly the point in time when we

are determining the future value, hence there is no interest on this deposit.

The future value of an annuity is the sum of the future value of each deposit:

Period	Amount of Deposit	Number of Periods Interest Is Earned	Compounding Factor	Future Value
1	\$1,000	4	1.2155	\$1,215.50
2	1,000	3	1.1576	1,157.60
3	1,000	2	1.1025	1,102.50
4	1,000	1	1.0500	1,050.00
5	1,000	0	1.0000	1,000.00
Total			5.5256	\$5,525.60

The future value of the series of \$1,000 deposits, with interest compounded at 5%, is \$5,525.60. Since we know the value of one of the level period flows is \$1,000, and the future value of the annuity is \$5,525.60, and looking at the sum of the individual compounding factors, 5.5256, we can see that there is an easier way to calculate the future value of an annuity. If the sum of the individual compounding factors for a specific interest rate and a specific number of periods were available, all we would have to do is multiply that sum by the value of one cash flow to get the future value of the entire annuity.

In this example, the shortcut is multiplying the amount of the annuity, \$1,000, by the sum of the compounding factors, 5.5256:

$$FV = \$1,000 \times 5.5256 = \$5,525.60$$

For large numbers of periods, summing the individual factors can be a bit clumsy—with possibilities of errors along the way. An alternative formula for the sum of the compound factors—that is, the future value annuity factor—is:

$$\text{Future value annuity factor} = \frac{(1+i)^N - 1}{i} \quad (10)$$

In the last example, $N = 5$ and $i = 5\%$:

$$\begin{aligned} \text{Future value annuity factor} &= \frac{(1+0.05)^5 - 1}{0.05} \\ &= \frac{1.2763 - 1.000}{0.05} \\ &= 5.5256 \end{aligned}$$

Let's use the long method to find the present value of the series of five deposits of \$1,000 each, with the first deposit at the end of the first period. Then we'll do it using the shortcut method. The calculations are similar to the future value of an ordinary annuity, except we are taking each deposit back in time, instead of forward:

Period	Amount of Deposit	Discounting Periods	Discounting Factor	Present Value
1	\$1,000	1	0.9524	\$952.40
2	1,000	2	0.9070	907.00
3	1,000	3	0.8638	863.80
4	1,000	4	0.8227	822.70
5	1,000	5	0.7835	783.50
Total			4.3294	\$4,329.40

The present value of this series of five deposits is \$4,329.40.

This same value is obtained by multiplying the annuity amount of \$1,000 by the sum of the discounting factors, 4.3294:

$$PV = \$1,000 \times 4.3294 = \$4,329.40$$

Another, more convenient way of solving for the present value of an annuity is to rewrite the factor as:

$$\text{Present value annuity factor} = \frac{1 - \frac{1}{(1+i)^N}}{i} \quad (11)$$

If there are many discount periods, this formula is a bit easier to calculate. In our last example,

$$\begin{aligned} \text{Present value annuity factor} &= \frac{\left[1 - \frac{1}{(1+0.05)^5}\right]}{0.05} \\ &= \frac{1 - 0.7835}{0.05} \\ &= 4.3295 \end{aligned}$$

which is different from the sum of the factors, 4.3294, due to rounding.

We can turn this present value of an annuity problem around to look at it from another angle. Suppose you borrow \$4,329.40 at an interest rate of 5% per period and are required to pay back this loan in five installments ($N = 5$): one payment per period for five periods, starting

one period from now. The payments are determined by equating the present value with the product of the cash flow and the sum of the discount factors:

$$\begin{aligned}
 PV &= CF(\text{sum of discount factors}) \\
 &= CF \sum_{t=1}^5 \frac{1}{(1 + 0.05)^t} \\
 &= CF (0.9524 + 0.9070 + 0.8638 + 0.8227 \\
 &\quad + 0.7835) \\
 &= CF (4.3294)
 \end{aligned}$$

substituting the known present value,

$$\$4,329.40 = CF (4.3294)$$

and rearranging to solve for the payment:

$$CF = \$4,329.40/4.3290 = \$1,000.00$$

We can convince ourselves that five installments of \$1,000 each can pay off the loan of \$4,329.40 by carefully stepping through the calculation of interest and the reduction of the principal:

Beginning of Periods Loan Balance	Payment	Interest (Principal × 5%)	Reduction in Loan Balance (Payment – Interest)	End-of-Period Loan Balance
\$4,329.40	\$1,000.00	\$216.47	\$783.53	\$3,545.87
3,545.87	1,000.00	177.29	822.71	2,723.16
2,723.16	1,000.00	136.16	863.84	1,859.32
1,859.32	1,000.00	92.97	907.03	952.29
952.29	1,000.00	47.61	952.29 ^a	0

^aThe small difference between calculated reduction (\$952.38) and reported reduction is due to rounding differences.

For example, the first payment of \$1,000 is used to: (1) pay interest on the loan at 5% (\$4,329.40 × 0.05 = \$216.47) and (2) pay down the principal or loan balance (\$1,000.00 – \$216.47 = \$783.53 paid off). Each successive payment pays off a greater amount of the loan—as the principal amount of the loan is reduced, less of each payment goes to paying off interest and more goes to reducing the loan principal. This analysis of the repayment of a loan is referred to as loan amortization. *Loan amortization*

is the repayment of a loan with equal payments, over a specified period of time. As we can see from the example of borrowing \$4,329.40, each payment can be broken down into its interest and principal components.

VALUING CASH FLOWS WITH DIFFERENT TIME PATTERNS

Valuing a Perpetual Stream of Cash Flows

There are some circumstances where cash flows are expected to continue forever. For example, a corporation may promise to pay dividends on preferred stock forever, or, a company may issue a bond that pays interest every six months, forever. How do you value these cash flow streams? Recall that when we calculated the present value of an annuity, we took the amount of one cash flow and multiplied it by the sum of the discount factors that corresponded to the interest rate and number of payments. But what if the number of payments extends forever—into infinity?

A series of cash flows that occur at regular intervals, forever, is a *perpetuity*. Valuing a perpetual cash flow stream is just like valuing an ordinary annuity. It looks like this:

$$\begin{aligned}
 PV &= CF_1 \left(\frac{1}{1+i} \right)^1 + CF_2 \left(\frac{1}{1+i} \right)^2 \\
 &\quad + CF_3 \left(\frac{1}{1+i} \right)^3 + \dots + CF_\infty \left(\frac{1}{1+i} \right)^\infty
 \end{aligned}$$

Simplifying, recognizing that the cash flows CF_t are the same in each period, and using summation notation,

$$PV = CF \sum_{t=1}^{\infty} \left(\frac{1}{1+i} \right)^t$$

As the number of discounting periods approaches infinity, the summation approaches $1/i$. To see why, consider the present value

annuity factor for an interest rate of 10%, as the number of payments goes from 1 to 200:

Number of Discounting Periods, N	Present Value Annuity Factor
1	0.9091
10	6.1446
40	9.7791
100	9.9993
200	9.9999

For greater numbers of payments, the factor approaches 10, or $1/0.10$. Therefore, the present value of a perpetual annuity is very close to:

$$PV = \frac{CF}{i} \quad (12)$$

Suppose you are considering an investment that promises to pay \$100 each period forever, and the interest rate you can earn on alternative investments of similar risk is 5% per period. What are you willing to pay today for this investment?

$$PV = \frac{\$100}{0.05} = \$2,000$$

Therefore, you would be willing to pay \$2,000 today for this investment to receive, in return, the promise of \$100 each period forever.

Let's look at the value of a perpetuity another way. Suppose that you are given the opportunity to purchase an investment for \$5,000 that promises to pay \$50 at the end of every period forever. What is the periodic interest per period—the return—associated with this investment?

We know that the present value is $PV = \$5,000$ and the periodic, perpetual payment is $CF = \$50$. Inserting these values into the formula for the present value of a perpetuity:

$$\$5,000 = \frac{\$50}{i}$$

Solving for i ,

$$i = \frac{\$50}{\$5,000} = 0.01 \text{ or } 1\% \text{ per period}$$

Therefore, an investment of \$5,000 that generates \$50 per period provides 1% compounded interest per period.

Valuing an Annuity Due

The ordinary annuity cash flow analysis assumes that cash flows occur at the end of each period. However, there is another fairly common cash flow pattern in which level cash flows occur at regular intervals, but the first cash flow occurs immediately. This pattern of cash flows is called an *annuity due*. For example, if you win the Florida Lottery Lotto grand prize, you will receive your winnings in 20 installments (after taxes, of course). The 20 installments are paid out annually, beginning immediately. The lottery winnings are therefore an annuity due.

Like the cash flows we have considered thus far, the future value of an annuity due can be determined by calculating the future value of each cash flow and summing them. And, the present value of an annuity due is determined in the same way as a present value of any stream of cash flows.

Let's consider first an example of the future value of an annuity due, comparing the values of an ordinary annuity and an annuity due, each comprising three cash flows of \$500, compounded at the interest rate of 4% per period. The calculation of the future value of both the ordinary annuity and the annuity due at the end of three periods is:

$$\begin{array}{ll} \text{Ordinary annuity} & \text{Annuity due} \\ FV = \$500 \sum_{t=1}^3 (1 + 0.04)^{3-t} & FV_{\text{due}} = \$500 \sum_{t=1}^3 (1 + 0.04)^{3-t+1} \end{array}$$

The future value of each of the \$500 payments in the annuity due calculation is compounded for one more period than for the ordinary annuity. For example, the first deposit of \$500 earns interest for two periods in the ordinary annuity situation [$\$500 (1 + 0.04)^2$], whereas the first \$500 in the annuity due case earns interest for three periods [$\$500 (1 + 0.04)^3$].

In general terms,

$$FV_{\text{due}} = CF \sum_{t=1}^N (1+i)^{N-t+1} \quad (13)$$

which is equal to the future value of an ordinary annuity multiplied by a factor of $1+i$:

$$FV_{\text{due}} = CF[\text{Future value annuity factor (ordinary) for } N \text{ and } i](1+i)$$

The present value of the annuity due is calculated in a similar manner, adjusting the ordinary annuity formula for the different number of discount periods:

$$PV_{\text{due}} = CF \sum_{t=1}^N \frac{1}{(1+i)^{t-1}} \quad (14)$$

Since the cash flows in the annuity due situation are each discounted one less period than the corresponding cash flows in the ordinary annuity, the present value of the annuity due is greater than the present value of the ordinary annuity for an equivalent amount and number of cash flows. Like the future value an annuity due, we can specify the present value in terms of the ordinary annuity factor:

$$PV_{\text{due}} = CF[\text{Present value annuity factor (ordinary) for } N \text{ and } i](1+i)$$

Valuing a Deterred Annuity

A *deferred annuity* has a stream of cash flows of equal amounts at regular periods starting at some time after the end of the first period. When we calculated the present value of an annuity, we brought a series of cash flows back to the beginning of the first period—or, equivalently the end of the period 0. With a deferred annuity, we determine the present value of the ordinary annuity and then discount this present value to an earlier period.

To illustrate the calculation of the present value of an annuity due, suppose you deposit \$20,000 per year in an account for 10 years, starting today, for a total of 10 deposits. What will

be the balance in the account at the end of 10 years if the balance in the account earns 5% per year? The future value of this annuity due is:

$$\begin{aligned} FV_{\text{due},10} &= \$20,000 \sum_{t=1}^{10} (1+0.05)^{10-t+1} \\ &= \$20,000 \left(\begin{array}{l} \text{Future value annuity} \\ \text{factor (ordinary) for} \\ \text{10 periods and 5\%} \end{array} \right) \\ &\quad \times (1+0.05) \\ &= \$20,000(12.5779)(1+0.05) = \$264,135.74 \end{aligned}$$

Suppose you want to deposit an amount today in an account such that you can withdraw \$5,000 per year for four years, with the first withdrawal occurring five years from today. We can solve this problem in two steps:

Step 1: Solve for the present value of the withdrawals.

Step 2: Discount this present value to the present.

The first step requires determining the present value of a four-cash-flow ordinary annuity of \$5,000. This calculation provides the present value as of the end of the fourth year (one period prior to the first withdrawal):

$$\begin{aligned} PV_4 &= \$5,000 \sum_{t=1}^4 \frac{1}{(1+0.04)^t} \\ &= \$5,000 (\text{present value annuity factor} \\ &\quad N = 4, i = 4\%) \\ &= \$18,149.48 \end{aligned}$$

This means that there must be a balance in the account of \$18,149.48 at the end of the fourth period to satisfy the withdrawals of \$5,000 per year for four years.

The second step requires discounting the \$18,149.48—the savings goal—to the present, providing the deposit today that produces the goal:

$$PV_0 = \frac{\$18,149.48}{(1+0.04)^4} = \$15,514.25$$

The balance in the account throughout the entire eight-year period is shown in Figure 6 with

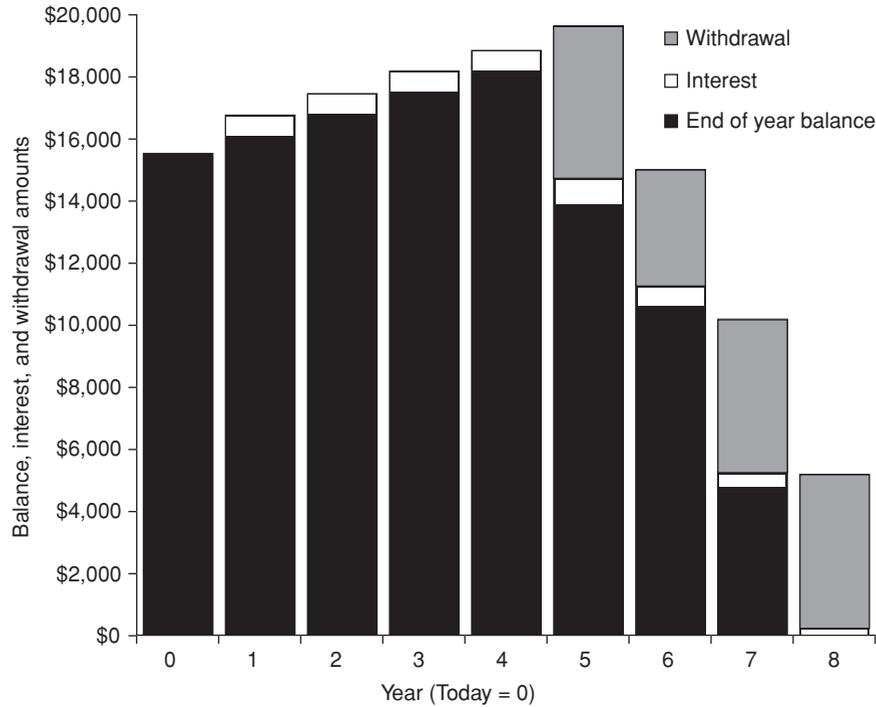

Figure 6 Balance in the Account that Requires a Deposit Today (Year 0) that Permits Withdrawals of \$5,000 Each Starting at the End of Year 4

the balance indicated both before and after the \$5,000 withdrawals.

Let's look at a more complex deferred annuity. Consider making a series of deposits, beginning today, to provide for a steady cash flow beginning at some future time period. If interest is earned at a rate of 4% compounded per year, what amount must be deposited in a savings account each year for four years, starting today, so that \$1,000 may be withdrawn each year for five years, beginning five years from today? As with any deferred annuity, we need to perform this calculation in steps:

Step 1: Calculate the present value of the \$1,000 per year five-year ordinary annuity as of the end of the fourth year:

The present value of the annuity deferred to the end of the fourth period is

$$\begin{aligned}
 PV_4 &= \$1,000 \sum_{t=1}^5 \frac{1}{(1 + 0.04)^t} = \$1,000(4.4518) \\
 &= \$4,451.80
 \end{aligned}$$

Therefore, there must be \$4,451.80 in the account at the end of the fourth year to permit five \$1,000 withdrawals at the end of each of the years 5, 6, 7, 8, and 9.

Step 2: Calculate the cash flow needed to arrive at the future value of that annuity due comprising four annual deposits earning 4% compounded interest, starting today.

The present value of the annuity at the end of the fourth year, \$4,451.80, is the future value of the annuity due of four payments of an unknown amount. Using the formula for the future value of an annuity due,

$$\begin{aligned}
 \$4,451.80 &= CF \sum_{t=1}^4 (1 + 0.04)^{4-t+1} \\
 &= CF (4.2465)(1.04)
 \end{aligned}$$

and rearranging,

$$CF = \$4,451.80 / 4.4164 = \$1,008.02$$

Therefore, by depositing \$1,008.02 today and the same amount on the same date each of the

next three years, we will have a balance in the account of \$4,451.80 at the end of the fourth period. With this period 4 balance, we will be able to withdraw \$1,000 at the end of the following five periods.

LOAN AMORTIZATION

There are securities backed by various types of loans. These include asset-backed securities, residential mortgage-backed securities, and commercial mortgage-backed securities. Consequently, it is important to understand the mathematics associated with loan amortization.

If an amount is loaned and then repaid in installments, we say that the loan is amortized. Therefore, *loan amortization* is the process of calculating the loan payments that amortize the loaned amount. We can determine the amount of the loan payments once we know the frequency of payments, the interest rate, and the number of payments.

Consider a loan of \$100,000. If the loan is repaid in 24 annual installments (at the end of each year) and the interest rate is 5% per year, we calculate the amount of the payments by applying the relationship:

$$\begin{aligned}
 PV &= \sum_{t=1}^N \frac{CF}{(1+i)^t} \\
 \text{Amount loaned} &= \sum_{t=1}^N \frac{\text{Loan payment}}{(1+i)^t} \\
 \$100,000 &= \sum_{t=1}^{24} \frac{\text{Loan payment}}{(1+0.05)^t}
 \end{aligned}$$

We want to solve for the loan payment, that is, the amount of the annuity. Using a financial calculator or spreadsheet, the periodic loan payment is \$7,247.09 ($PV = \$100,000$; $N = 24$; $i = 5\%$). Therefore, the monthly payments are \$7,247.09 each. In other words, if payments of \$7,247.09 are made each year for 24 years (at the end of each year), the \$100,000 loan will be repaid and the lender earns a return that is equivalent to a 5% interest on this loan.

We can calculate the amount of interest and principal repayment associated with each loan

payment using a loan amortization schedule, as shown in Table 1.

The loan payments are determined such that after the last payment is made there is no loan balance outstanding. Thus, the loan is referred to as a *fully amortizing loan*. Even though the loan payment each year is the same, the proportion of interest and principal differs with each payment: The interest is 5% of the principal amount of the loan that remains at the beginning of the period, whereas the principal repaid with each payment is the difference between the payment and the interest. As the payments are made, the remainder is applied to repayment of the principal; this is referred to as the scheduled principal repayment or the *amortization*. As the principal remaining on the loan declines, less interest is paid with each payment. We show the decline in the loan's principal graphically in Figure 7. The decline in the remaining principal is not a linear, but is curvilinear due to the compounding of interest.

Loan amortization works the same whether this is a mortgage loan, a term loan, or any other loan in which the interest paid is determined on the basis of the remaining amount of the loan. The calculation of the loan amortization can be modified to suit different principal repayments, such as additional lump-sum payments, known as *balloon payments*. For example, if there is a \$10,000 balloon payment at the end of the loan in the loan of \$100,000 repaid over 24 years, the calculation of the payment is modified as:

$$\begin{aligned}
 \text{Amount loaned} &= \left[\sum_{t=1}^N \frac{\text{Loan payment}}{(1+i)^t} \right] + \frac{\text{balloon payment}}{(1+i)^N} \\
 \$100,000 &= \left[\sum_{t=1}^{24} \frac{\text{Loan payment}}{(1+0.05)^t} \right] + \frac{\$10,000}{(1+i)^{24}}
 \end{aligned}$$

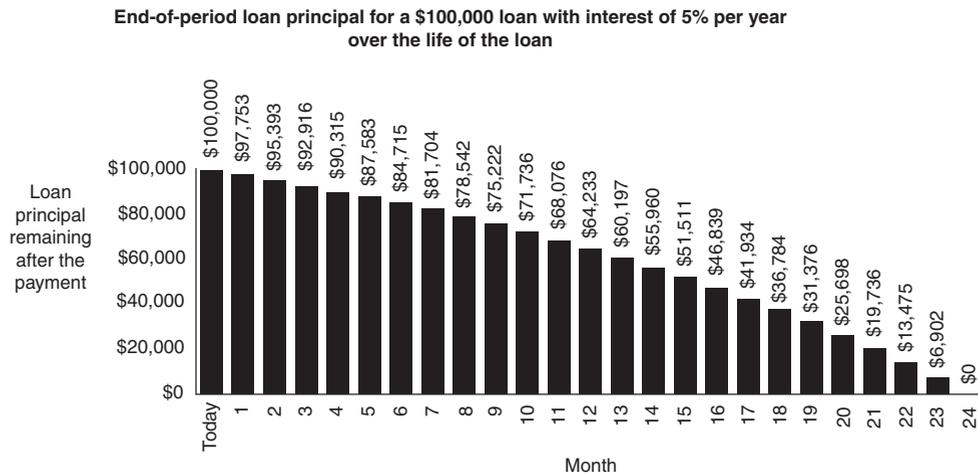

The loan payment that solves this equation is \$7,022.38 ($PV = \$100,000$; $N = 24$; $i = 5\%$; $FV = \$10,000$). The last payment (that is, at the

Table 1 Loan Amortization on a \$100,000 Loan for 24 Years and an Interest Rate of 5% per Year

Payment	Loan Payment	Beginning-of-the-Year Principal	Interest on Loan	Principal Paid Off = Payment – Interest	Remaining Principal
0					\$100,000.00
1	\$7,247.09	\$100,000.00	\$5,000.00	\$2,247.09	\$97,752.91

18	\$7,247.09	\$41,934.37	\$2,096.72	\$5,150.37	\$36,784.00
19	\$7,247.09	\$36,784.00	\$1,839.20	\$5,407.89	\$31,376.11
20	\$7,247.09	\$31,376.11	\$1,568.81	\$5,678.28	\$25,697.83
21	\$7,247.09	\$25,697.83	\$1,284.89	\$5,962.20	\$19,735.63
22	\$7,247.09	\$19,735.63	\$986.78	\$6,260.31	\$13,475.32
23	\$7,247.09	\$13,475.32	\$673.77	\$6,573.32	\$6,901.99
24	\$7,247.09	\$6,901.99	\$345.10	\$6,901.99	\$0.00

end of the 24th year) is the regular payment of \$7,022.38, plus the balloon payment, for a total of \$17,022.38. As you can see in Figure 8, the loan amortization is slower when compared to the loan without the balloon payment.

The same mathematics work with term loans. Term loans are usually repaid in installments either monthly, quarterly, semiannually, or annually. Let's look at the typical repayment schedule for a term loan. Suppose that BigRock

**Figure 7** Loan Amortization

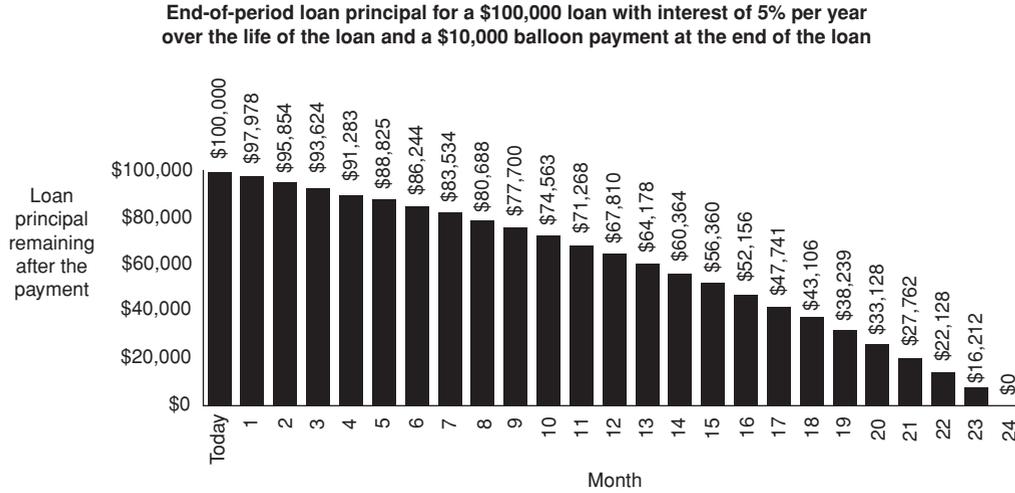

Figure 8 Loan Amortization with Balloon Payment

Corporation seeks a four-year term loan of \$100 million. Let’s assume for now that the term loan carries a fixed interest rate of 8% and that level payments are made monthly. If the annual interest rate is 8%, the rate per month is $8\% \div 12 = 0.6667\%$ per month. In a typical term loan, the payments are structured such that the loan is fully amortizing.

For this four-year, \$100 million term loan with an 8% interest rate, the monthly payment is \$2,441,292.23 ($PV = \$100,000,000; N = 48; i = 0.6667\%$). This amount is determined by solving for the annuity payment that equates the present value of the payments with the amount of the loan, considering a discount rate of 0.6667%. In Table 2 we show for each month the beginning monthly balance, the interest payment for the month, the amount of the monthly, and the ending loan balance. Notice that in our illustration, the ending loan balance is zero. That is, it is a fully amortizing loan.

In the loan amortization examples so far, we have assumed that the interest rate is fixed throughout the loan. However, in many loans the interest rate may change during the loan, as in the case of a floating-rate loan. The new loan rate at the reset date is determined by a formula. The formula is typically composed of two parts. The first is the reference rate. For

example, in a monthly pay loan, the loan rate might be one-month London Interbank Offered Rate (LIBOR). The second part is a spread that is added to the reference rate. This spread is referred to as the quoted margin and depends on the credit of the borrower.

A floating-rate loan requires a recalculation of the loan payment and payment schedule at each time the loan rate is reset. Suppose in the case of BigRock’s term loan that the rate remains constant for the first three years, but is reset to 9% in the fourth year. This requires BigRock to pay off the principal remaining at the end of three years, the \$28,064,562.84, in the remaining 12 payments. The revised schedule of payments and payoff for the fourth year require a payment of \$2,454,287.47 ($PV = \$27,064,562.84; N = 12; i = 0.09 \div 12 = 0.75\%$), as shown in Table 3.

THE CALCULATION OF INTEREST RATES AND YIELDS

The calculation of the present or future value of a lump-sum or set of cash flows requires information on the timing of cash flows and the compound or discount rate. However, there are

Table 2 Term Loan Schedule: Fixed Rate, Fully Amortized

Monthly Payment	Beginning-of-the-Year Principal	Interest on Loan	Principal Paid Off = Payment – Interest	Remaining Principal
	\$100,000,000			
	Interest rate	8% per year		
	Number of years	4		
	Monthly payment	\$2,441,292.33		
1	\$100,000,000.00	\$666,666.67	\$1,774,625.57	\$98,225,374.43
2	\$98,225,374.43	\$654,835.83	\$1,786,456.40	\$96,438,918.03

many applications in which we are presented with values and cash flows, and wish to calculate the yield or implied interest rate associated with these values and cash flows. By calculating the yield or implied interest rate, we can then compare investment or financing opportunities. We first look at how interest rates are stated and how the effective interest rate can be calculated based on this stated rate, and then we look at how to calculate the yield, or rate of return, on a set of cash flows.

Annual Percentage Rate versus Effective Annual Rate

A common problem in finance is comparing alternative financing or investment opportunities when the interest rates are specified in a way that makes it difficult to compare terms. The Truth in Savings Act requires institutions to provide the annual percentage yield for savings accounts. As a result of this law, consumers can compare the yields on different savings arrangements. But this law does not apply beyond savings accounts. One investment may pay 10% interest compounded semiannually, whereas another investment may pay 9% interest compounded daily. One financing ar-

agement may require interest compounding quarterly, whereas another may require interest compounding monthly. To compare investments or financing with different frequencies of compounding, we must first translate the stated interest rates into a common basis. There are two ways to convert interest rates stated over different time intervals so that they have a common basis: the annual percentage rate and the effective annual interest rate.

One obvious way to represent rates stated in various time intervals on a common basis is to express them in the same unit of time—so we annualize them. The annualized rate is the product of the stated rate of interest per compound period and the number of compounding periods in a year. Let i be the rate of interest per period and n be the number of compounding periods in a year. The annualized rate, also referred to as the *nominal interest rate* or the annual percentage rate (APR) is:

$$\text{APR} = i \times n$$

Consider the following example. Suppose the Lucky Break Loan Company has simple loan terms: Repay the amount borrowed, plus 50%, in six months. Suppose you borrow \$10,000 from Lucky. After six months, you must pay

back the \$10,000 plus \$5,000. The APR on financing with Lucky is the interest rate per period (50% for six months) multiplied by the number of compound periods in a year (two six-month periods in a year). For the Lucky Break financing arrangement:

$$\text{APR} = 0.50 \times 2 = 1.00 \text{ or } 100\% \text{ per year}$$

But what if you cannot pay Lucky back after six months? Lucky will let you off this time, but you must pay back the following at the end of the next six months:

- The \$10,000 borrowed.
- The \$5,000 interest from the first six months.
- The 50% of interest on both the unpaid \$10,000 and the unpaid \$5,000 interest (\$15,000 (0.50) = \$7,500).

So, at the end of the year, knowing what is good for you, you pay off Lucky:

Amount of the original loan	\$10,000
Interest from first six months	5,000
Interest on second six months	7,500
	\$22,500
Total payment at end of the year	\$22,500

Using the Lucky Break method of financing, you have to pay \$12,500 interest to borrow \$10,000 for one year's time. Because you have to pay \$12,500 interest to borrow \$10,000 over one year's time, you pay not 100% interest, but rather 125% interest per year (\$12,500/\$10,000 = 1.25 = 125%). What's going on here? It looks like the APR in the Lucky Break example ignores the compounding (interest on interest) that takes place after the first six months. And that's the way it is with all APRs. The APR ignores the effect of compounding. Therefore, this rate understates the true annual rate of interest if interest is compounded at any time prior to the end of the year. Nevertheless, APR is an acceptable method of disclosing interest on many lending arrangements, since it is easy to understand and simple to compute. However, because it ignores compounding, it is not the best way to convert interest rates to a common basis.

Another way of converting stated interest rates to a common basis is the effective rate of interest. The *effective annual rate* (EAR) is the true economic return for a given time period—it takes into account the compounding of interest—and is also referred to as the effective rate of interest.

Using our Lucky Break example, we see that we must pay \$12,500 interest on the loan of \$10,000 for one year. Effectively, we are paying 125% annual interest. Thus, 125% is the effective annual rate of interest. In this example, we can easily work through the calculation of interest and interest on interest. But for situations where interest is compounded more frequently, we need a direct way to calculate the effective annual rate. We can calculate it by resorting once again to our basic valuation equation:

$$FV = PV(1 + i)^n$$

Next, we consider that a return is the change in the value of an investment over a period and an annual return is the change in value over a year. Using our basic valuation equation, the relative change in value is the difference between the future value and the present value, divided by the present value:

$$\text{EAR} = \frac{FV - PV}{PV} = \frac{PV(1 + i)^n}{PV}$$

Canceling PV from both the numerator and the denominator,

$$\text{EAR} = (1 + i)^n - 1 \quad (15)$$

Let's look how the EAR is affected by the compounding. Suppose that the Safe Savings and Loan promises to pay 6% interest on accounts, compounded annually. Since interest is paid once, at the end of the year, the effective annual return, EAR, is 6%. If the 6% interest is paid on a semiannual basis—3% every six months—the effective annual return is larger than 6% since interest is earned on the 3% interest earned at the end of the first six months. In this case, to calculate the EAR, the interest rate per compounding period—six months—is 0.03

(that is, $0.06/2$) and the number of compounding periods in an annual period is 2:

$$\text{EAR} = (1 + 0.03)^2 - 1 = 1.0609 - 1 = 0.0609$$

or 6.09%

Extending this example to the case of quarterly compounding with a nominal interest rate of 6%, we first calculate the interest rate per period, i , and the number of compounding periods in a year, n :

$$i = 0.06/4 = 0.015 \text{ per quarter}$$

$$n = 4 \text{ quarters in a year}$$

The EAR is:

$$\text{EAR} = (1 + 0.015)^4 - 1 = 1.0614 - 1 = 0.0614$$

or 6.14%

As we saw earlier, the extreme frequency of compounding is continuous compounding. Continuous compounding is when interest is compounded at the smallest possible increment of time. In continuous compounding, the rate per period becomes extremely small:

$$i = \frac{\text{APR}}{\infty}$$

And the number of compounding periods in a year, n , is infinite. The EAR is therefore:

$$\text{EAR} = e^{\text{APR}} - 1 \tag{16}$$

where e is the natural logarithmic base.

For the stated 6% annual interest rate compounded continuously, the EAR is:

$$\text{EAR} = e^{0.06} - 1 = 1.0618 - 1 = 0.0618 \text{ or } 6.18\%$$

The relation between the frequency of compounding for a given stated rate and the effective annual rate of interest for this example indicates that the greater the frequency of compounding, the greater the EAR.

Frequency of Compounding	Calculation	Effective Annual Rate
Annual	$(1 + 0.060)^1 - 1$	6.00%
Semiannual	$(1 + 0.030)^2 - 1$	6.09%
Quarterly	$(1 + 0.015)^4 - 1$	6.14%
Continuous	$e^{0.06} - 1$	6.18%

Figuring out the effective annual rate is useful when comparing interest rates for different investments. It doesn't make sense to compare the APRs for different investments having a different frequency of compounding within a year. But since many investments have returns stated in terms of APRs, we need to understand how to work with them.

To illustrate how to calculate effective annual rates, consider the rates offered by two banks, Bank A and Bank B. Bank A offers 9.2% compounded semiannually and Bank B other offers 9% compounded daily. We can compare these rates using the EARs. Which bank offers the highest interest rate? The effective annual rate for Bank A is $(1 + 0.046)^2 - 1 = 9.4\%$. The effective annual rate for Bank B is $(1 + 0.000247)^{365} - 1 = 9.42\%$. Therefore, Bank B offers the higher interest rate.

Yields on Investments

Suppose an investment opportunity requires an investor to put up \$1 million and offers cash inflows of \$500,000 after one year and \$600,000 after two years. The return on this investment, or *yield*, is the discount rate that equates the present values of the \$500,000 and \$600,000 cash inflows to equal the present value of the \$1 million cash outflow. This yield is also referred to as the *internal rate of return* (IRR) and is calculated as the rate that solves the following:

$$\$1,000,000 = \frac{\$500,000}{(1 + \text{IRR})^1} + \frac{\$600,000}{(1 + \text{IRR})^2}$$

Unfortunately, there is no direct mathematical solution (that is, closed-form solution) for the IRR, but rather we must use an iterative procedure. Fortunately, financial calculators and financial software ease our burden in this calculation. The IRR that solves this equation is 6.3941%:

$$\$1,000,000 = \frac{\$500,000}{(1.063941)^1} + \frac{\$600,000}{(1.063941)^2}$$

In other words, if you invest \$1 million today and receive \$500,000 in one year and \$600,000

in two years, the return on your investment is 6.3941%.

Another way of looking at this same yield is to consider that an investment's IRR is the discount rate that makes the present value of all expected future cash flows—both the cash outflows for the investment and the subsequent inflows—equal to zero. We can represent the IRR as the rate that solves:

$$\$0 = \sum_{t=1}^N \frac{CF_t}{(1 + \text{IRR})^t}$$

Consider another example. Suppose an investment of \$1 million produces no cash flow in the first year but cash flows of \$200,000, \$300,000, and \$900,000 two, three, and four years from now, respectively. The IRR for this investment is the discount rate that solves:

$$0 = \frac{\$1,000,000}{(1 + \text{IRR})^0} + \frac{0}{(1 + \text{IRR})^1} + \frac{\$200,000}{(1 + \text{IRR})^2} + \frac{\$300,000}{(1 + \text{IRR})^3} + \frac{\$900,000}{(1 + \text{IRR})^4}$$

Using a calculator or a computer, we get the precise answer of 10.172% per year.

We can use this approach to calculate the yield on any type of investment, as long as we know the cash flows—both positive and negative—and the timing of these flows. Consider the case of the yield to maturity on a bond. Most bonds pay interest semiannually—that is, every six months. Therefore, when calculating the yield on a bond, we must consider the timing of the cash flows to be such that the discount period is six months.

Consider a bond that has a current price of 90; that is, if the par value of the bond is \$1,000, the bond's price is 90% of \$1,000 or \$900. And suppose that this bond has five years remaining to maturity and an 8% coupon rate. With five years remaining to maturity, the bond has 10 six-month periods remaining. With a coupon rate of 8%, this means that the cash flows for

interest is \$40 every six months. For a given bond, we therefore have the following information:

1. Present value = \$900
2. Number of periods to maturity = 10
3. Cash flow every six months = \$40
4. Additional cash flow at maturity = \$1,000

The six-month yield, r_d , is the discount rate that solves the following:

$$\$900 = \left[\sum_{t=1}^{10} \frac{\$40}{(1 + r_d)^t} \right] + \frac{\$1,000}{(1 + r_d)^{10}}$$

Using a calculator or spreadsheet, the six-month yield is 5.315%. Bond yields are generally stated on the basis of an annualized yield, referred to as the yield to maturity (YTM) on a bond-equivalent basis. This YTM is analogous to the APR with semiannual compounding. Therefore, yield to maturity is 10.63%.

KEY POINTS

- A present value can be translated into a value in the future through compounding. The extreme frequency of compounding is continuous compounding.
- A future value can be converted into an equivalent value today through discounting.
- Applications in finance may require the determination of the present or future value of a series of cash flows rather than simply a single cash flow. The principles of determining the future value or present value of a series of cash flows are the same as for a single cash flow. That is, any number of cash flows can be translated into a present or future value.
- When faced with a series of cash flows, a financial modeler must value each cash flow individually, and then sum these individual values to arrive at the present value of the series.

- The tools of the time value of money can be used to value many different patterns of cash flows, including perpetuities, annuities due, and deferred annuities. Applying the tools to these different patterns of cash flows requires specifying the timing of the various cash flows.
- The interest on alternative investments is stated in different terms, so these interest rates must be placed on a common basis so that investment alternatives can be compared. Typically, an interest rate on an annual basis is specified, using either the annual percentage rate or the effective annual rate. The latter method is preferred since it takes into consideration the compounding of interest within a year.
- The yield on an investment (also referred to as internal rate of return) is the interest rate that makes the present value of the future cash flows equal to the cost of the investment.

NOTE

1. For a more detailed treatment of this topic, see Drake and Fabozzi (2009). The topic is covered in finite mathematics textbooks. See, for example, Barnett, Ziegler, and Byleen (2002), Mizrahi and Sullivan (1999), and Rolf (2007).

Fundamentals of Matrix Algebra

SERGIO M. FOCARDI, PhD
Partner, The Intertek Group

FRANK J. FABOZZI, PhD, CFA, CPA
Professor of Finance, EDHEC Business School

Abstract: Ordinary algebra deals with operations such as addition and multiplication performed on individual numbers. In many applications, however, it is useful to consider operations performed on ordered arrays of numbers. This is the domain of matrix algebra. Ordered arrays of numbers are called vectors and matrices while individual numbers are called scalars.
